More than in Part 2 he is concerned with individuals and the extensive record of their work. To follow all of these one needs to know a great deal of chemistry. It will not be easy going for those who do not. As in previous volumes one finds light being shed on Western science. For example, in dealing with Ko Hung, a great alchemist, and his contemporaries, Needham says "How did they keep their heads in the midst of so much religious-magical enthusiasm? How did he manage to make so many true observations of chemical behaviour, and carry out so many interpretable experiments even though he himself could never interpret them? . . . Ko Hung had one eye on the magic, the sacrifices, the Taoist temple liturgies but he kept the other firmly fixed on the real changes and transformations which he observed at his bench and his furnaces". We could apply this analysis to much that is puzzling in Western practice not only in the obviously related field of Western

A woman alchemist, possibly Thai Hsüan Nü, compounding elixirs. Taken from the Lieh Hsien Chhüan Chuan (Complete Collection of the Biographies of the Immortals), Ming, about 1580 AD.

alchemy and chemistry, but much other science and proto-science.

The fate of alchemy in China is curiously parallel with its fate in the West. It declined through the Middle Ages and was made the subject of satire. There was even a kind of iatrochemistry as its successor. But instead of a continuous suppression of alchemy by a progressive modern chemistry, there came a gap. Western chemistry was introduced into China bit by bit, to be adapted and assimilated like many other foreign influences, so that in

China, it seems, modern chemistry is the heir of the West, not of the remarkable, indigenous chemistry with which the major part of this book is concerned.

The title suggests that Needham has told a continuous story, but in fact he says plainly that he is not dealing with modern chemistry; the detailed treatment stops at the end of the eighteenth century, with only a few pages on the modern sinisation of terminology, but any more than we are offered would be indigestible.

There is one thing to regret. Needham refers to early illustrations of chemical apparatus but they are not reproduced. Perhaps it was not possible. There is, however, always work to do and we shall look forward to seeing them another time. The general impression is of the predominance of elixir-seeking in Chinese alchemy, and its relationship to the Chinese attitude to length of life as a virtue as well as an advantage. Resemblance to Western alchemy often arises from the fact that the Chinese were dealing with the same chemical substances, so that what they could discover and what they could infer was bound to be the same in the West. But the differences lay in the civilisation itself. Thus, the common ground of science enables one the better to understand what was distinctive in the civilisation. This justifies, if nothing else does, the title of the whole enterprise.

Frank Greenaway

Frank Greenaway is Keeper of the Department of Chemistry at the Science Museum, London, UK.

General relativity for undergraduates

Gravitation and Spacetime. By Hans C. Ohanian. Pp. xiv+461. (Norton: New York, May 1976.) \$18.95.

OVER the past decade there has been an explosion of discoveries, both theoretical and observational, in the subjects of gravity and relativity. Yet curiously there are still very few well written, broadly based and concise introductory books on general relativity which cover these exciting new developments. Perhaps this reflects the tradition of regarding general relativity as primarily a postgraduate and research activity; but increasingly in recent years, universities and colleges are running general relativity courses for undergraduates. This book by Ohanian is ideally suited to such courses as a teaching textbook.

The flavour of the book which emerges, suggests that it is aimed primarily at the physics student. The mathemati-

cal development of the subject matter is competent, and quite adequate for physicists, but perhaps a little sparing for mathematics students primarily interested in the modern techniques of differential geometry and topology, the singularity theorems, and so on.

The book contains much interesting discussion of experimental techniques and results. The later chapters cover modern developments in black hole theory and cosmology. There is little in the way of special relativity.

Many people will find this book useful for reference. Information retrieval is easy, the presentation of the material clear, concise and accurate; students should have little difficulty in finding their way around the subject matter, and exercises are plentiful.

In short, a solid, direct and informative reference and teaching book to be recommended to all students of relativity.

Paul Davies

Paul Davies is a Lecturer in the Department of Mathematics at King's College, University of London, UK.

Parvoviruses

The Parvoviruses. (Virology Monographs/Die Virusforschung in Einzeldarstellungen, Vol. 15.) By G. Siegl. Pp. iv+109. (Springer: Wien and New York, 1976.) DM56; \$3.86.

THIS excellent little monograph reviews information on known members of the genus *Parvovirus* in the Family Parvoviridae. The volume of data accumulated during the past decade on members of this genus is so great (over 300 major references), and is so complex, that Dr Siegl has wisely concentrated on this genus, leaving information on the genera *Adeno-associated virus* and *Densovirus* to subsequent reviewers.

The intense interest engendered in this newly discovered family of viruses derives from their unique structure, a single-stranded DNA molecule capable of coding for only 3–5 proteins being enclosed in a 20-nm protein capsid. The dynamics of replication of such a single-stranded DNA in eukaryotic cells has provided an exciting challenge, and offered an ideal experimental system to study biochemical processes which occur during replication of DNA viruses.

For each of the nine members of the genus, Dr Siegl traces the work which has led to the finding that these viruses require cellular helper effects to replicate, and in consequence multiply only in actively dividing tissues. Although only two of the nine members have as yet been shown of importance in natural disease, the results of fundamental research on the 'important' members have shown these viruses to have a unique pathogenesis, selectively attacking foetal, neonatal, intestinal and haemopoietic tissue. This finding has in turn stimulated applied virologists to search for disease syndromes to associate with other members of this genus.

Dr Siegl has presented his review in sections, dealing with each virus on a species basis. Although this approach has inevitably led to some duplication of general information, it provides for easy reference by the species specialist, and certainly minimises the confusion associated with some members of the genus. Such complex data are particularly evident for the section on hamster osteolytic parvoviruses, and for those viruses which have been found as contaminants of cell lines. The review given for the porcine parvovirus has been subsequently developed (see Joo and Johnson, *Porcine Parvovirus—A Review*, *Vet. Bull.*, **46**, 653; 1976), and this virus has now been shown to

be a significant cause of natural reproductive failure.

Although information on the significance in nature of the porcine parvovirus and the feline virus have now clearly been established and control measures undertaken, it is disappointing to the reviewer as an applied worker, to see the paucity of information available on the disease significance of the bovine and canine parvoviruses. It is hoped that the future may see as detailed and conscientious a study of the significance of these viruses, and of possible human parvoviruses, as has been presented by the fundamentalists for the rodent viruses.

Although not in any way wishing to detract from the value of the monograph, the reviewer would have welcomed wider discussion and speculation by such a respected authority as Dr Siegl, and a gentle rebuke is included for the publishers in allowing printing of this excellent work without any obvious attempt to correct spelling and grammar.

Prostaglandins

Prostaglandins: Chemical and Biochemical Aspects. Pp. xiii+252. £9.95. *Prostaglandins: Physiological, Pharmacological and Pathological Aspects.* Pp. x+367. £11.50. *Prostaglandins and Reproduction.* Pp. x+332. £11.50. (Advances in Prostaglandin Research.) Edited by S. M. M. Karim. (MTP: Lancaster, 1975–76.)

As Professor Karim points out in his introduction, it is now impossible to comprehensively cover the entire prostaglandin field in one volume; this latest contribution is accordingly divided into three parts. The complete set comprises more than 20 chapters written with varying degrees of clarity by almost 30 specialists.

Part I surveys current understanding of the role of prostaglandins in reproduction. There is a general discussion of the role of prostaglandins in the reproductive physiology of man (Karim and Hillier), subhuman primates (Kirton), laboratory (Labhsetwar) and some domestic animals (Flint and Hillier). There are also chapters on the use of prostaglandins to induce labour (Thiery and Amy) and to interrupt pregnancy (Karim and Amy). This volume concludes with an interesting chapter on the use of prostaglandins

and their analogues in animal husbandry (Cooper and Walpole).

Part II deals with the more basic chemical and biochemical aspects of prostaglandin research, beginning with a review by Schneider of chemical synthetic methods for prostaglandins. The methodological information in the chapter on prostaglandin analysis by Salmon and Karim is particularly welcome, as is a thoughtful contribution by Lands and Rome on inhibition of prostaglandin biosynthesis. Sanner and Eakins review prostaglandin antagonists, and in the final chapter Kuehl, Cirillo and Oien attempt to clarify the confused area of prostaglandin–cyclic nucleotide interactions.

Physiological, pharmacological and pathological aspects of prostaglandins are covered in Part III, with interesting chapters on the role of prostaglandins in the central nervous system (Cocconi and Pace-Asciak), autonomic neurotransmission (Hedqvist), ocular (Eakins), gastrointestinal (Bennett), renal and cardiovascular (McGiff and Malik) as well as respiratory (Smith) physiology and blood coagulation (Howie). There is a rather short discussion on prostaglandins in inflammation (Greaves) and a welcome review of prostaglandins in tumours (Karim and Rao); this volume concludes with a useful review of the pharmacology of prostaglandin analogues (Karim and Ganesan Adaikan).

In rapidly developing areas, it is always difficult for reviewers to incorporate the most recent developments. Since 1974, there has been accumulating evidence that in some tissues, a large proportion of prostaglandin endoperoxides are metabolised to non-prostaglandin end-products and that in some cells (for example, platelets) the major biological actions are almost certainly due to the endoperoxides rather than the 'primary prostaglandins' E and F. This important idea was neglected by several contributors. It is regrettable—but unavoidable—that details of the most recent endoperoxide rearrangement products, the thromboxanes, could not be included.

I found this series worthwhile. It contains an abundance of up-dated material and covers much ground never before reviewed. The volumes have been well produced and the standard of the printing and illustrations was generally good, although there were some badly drawn structural formulae in one chapter. These volumes will be a useful addition to any departmental library; the cost of the series puts it beyond the pocket of most individuals.

R. J. Flower

Roderick Flower is a research pharmacologist with the Wellcome Foundation, Beckenham, UK.

Agronomy and nutrition of maize

Mineral Nutrition of Maize. By I. Arnon. Pp. 452. (International Potash Institute: Bern-Worblaufen, Switzerland, 1976.)

THIS excellent volume is really two books in one, covering both agronomy of maize and general plant nutrition and fertiliser use with maize as an example. Following an introductory chapter on the origins, economic importance and botanical characteristics of this crop come several chapters discussing, in some detail, methods for maize production. These include sections on cropping systems, rotations, tillage practice, planting, control of weeds, pests and diseases, irrigation and harvesting.

The author reviews the most recent developments in these—for example, minimum tillage and use of herbicides—and draws together information from many parts of the world in discussing their impact on maize growing. A brief chapter on the general nutritional requirements of maize leads to a treatment of the nutrient supplying power of soil and the dynamics of nutrient uptake that would not be out of place in a soil science textbook.

The author is to be congratulated on the clear way in which relatively new concepts of the plant-root system are presented. As the author points out in the foreword, "more fertilisers are probably used for maize than for any other annual crop" and with "its high yield potential, the maize plant has been subjected to more research than most other crop plants". The results of this research have been excellently compiled in chapters dealing with the effects of fertilisers on yields and crop quality, on the important matter of interactions between nutrient elements and on practical aspects of fertiliser use such as soil testing, choice of fertilisers and methods and timing of applications.

Particular attention is paid to the relationship between fertiliser use and the local environment, management practices and maize varieties. Although concentrating on maize, these chapters deal with basic principles of fertiliser use which are relevant to many other crops and situations, making the book valuable even to those not directly interested in maize itself.

The entire book is a fine blend of scientific principles, research findings and practical aspects of crop production that should make it a welcome addition to the bookshelves of anyone

whose interest is in agricultural development. It is well produced, with many graphs, diagrams and tables, and several photographs including some in colour. The only criticism is the lack of an index, or even a list of illustrations, but the overall planning of the chapters makes it relatively easy to find the information required.

Stuart G. McRae

Stuart McRae is a Lecturer in Soil Science at Wye College, University of London, UK.

Phosphorus chemistry

The Chemistry of Phosphorus: Environmental, Organic, Inorganic, Biochemical and Spectroscopic Aspects. By John Emsley and Dennis Hall. Pp. xi+563. (Harper and Row: London and New York, July 1976.) £22.50; \$39.50.

SINCE the appearance about fifteen years ago of the monumental two-volume treatise by Van Wazer on *Phosphorus and its Compounds*, there has been a veritable explosion of monographs and series devoted to various aspect of this important element. Sasse, Hudson, Mann, Corbridge, Allcock, Kosolapoff and Maier (seven edited volumes); *Topics in Phosphorus Chemistry*, and *Organophosphorus Chemistry* (Annual Specialists Reports by the Chemical Society) are just a few of these solely devoted to various aspects of this subject.

Phosphorus chemistry in all its branches—biochemical, organic, inorganic, pure and applied—has made very great strides. Even so, one must closely scrutinise the appearance of a new book, particularly in a field in which so many authors with an international reputation have already put pen to paper. This is particularly pertinent at a time, when one has annually the unpleasant task of deciding which journal subscription has to be cancelled and to choose the very few books (from a long list) the library can afford to purchase (most monographs have already priced themselves out of the market for the individual buyer). As a contributor to Kosolapoff and Maier, I am aware of the pitifully small number of volumes of the standard reference treatise in an important field, which have been sold.

Professor Denney, in the preface, mentions that this is the first book attempting to bring together the various aspects of phosphorus chemistry under one cover. This is indeed the case. But for whom is this book in-

tended? Even a devotee of the subject like myself would hesitate to recommend a book of over 500 pages to undergraduates; it is an important and fascinating facet of Chemistry, but so are many others! In any case they could not afford it. The specialist research workers would require considerably more detail than could possibly have been given in a book of this size. A multi-authored multi-volume treatise would be required for them, but at a price at which most libraries would balk.

I found the book easy to read, although traditionalists might object to colloquialisms, such as: "This suggests that what (POPh)₃ loses on the δ swings it gains on the π roundabouts". I have learned something from sections, where my knowledge is cursory; I was disappointed in those the contents of which I know well. Perhaps this is inevitable in a book of this size.

The authors do not state up to which date they have covered the literature; my own impression is up to 1972, with some references either to secondary sources or to some selected research teams beyond that (mainly 1973). This is probably not the authors' fault; there are inordinate delays in the publication processes for both books and journals.

Obviously in a book of this size one cannot please everybody. Westheimer's work on the hydrolysis of cyclic phosphorus esters is covered, but Wolf's work on spiroposphoranes is hardly touched. The section on nuclear magnetic resonance spectra is thin, and no mention is made of Harris' important work on second-order phenomena. The industrially vital phosphates are barely touched; and Corey's work on the Wittig reaction, and Niecke's and Scherer's work on the isolation (of the hitherto only postulated) three-coordinate five-valent phosphorus species receive no mention. Misinterpretations and misquotations of the literature will be found by the expert eye.

In spite of the above criticism, it would be churlish not to acknowledge the tremendous time and effort the authors have expended on their task, and when used with discretion this book will be useful to some readers.

Although I enjoyed reading the book, the lingering doubt remains: whether the treatment of a subject with this scope in mind, would not have been better served as a "Current Awareness" book at a quarter, or even less, of its length and price, which would then have suited undergraduates and the general scientific reader. R. A. Shaw

Robert Shaw is Professor of Chemistry at Birkbeck College, University of London, UK.

nature

November 25, 1976

Half greater than whole

WITH the steady decline in the number of those who go into productive industry in Britain and the steady rise in the number of people worrying about the problem, before the end of the century we expect these numbers to be equal and sometime early in the twenty-first century to see the disappearance of the last industrial worker. The Commons Select Committee on Science and Technology is the latest to agonise over the trend (Commons paper 680, £1.15), and if anything may have helped to speed it on its way by publishing some bitter remarks from some of its witnesses. From Lord Bowden, formerly Principal of the University of Manchester Institute of Science and Technology, for example, about the hazards of industrial life, the rather unpleasant environment and the contempt of society at large for those who create the wealth which everyone wants to spend. Or from the Chairman of EMI, who declared that you wouldn't choose the industrial environment for security, money or professional satisfaction. Or even from Mr Varley, the Secretary of State for Industry, who said that 'to be a technologist or a manager within industry has been a pretty lousy job'.

The committee, in looking at university-industry relations, has bitten off more than it can reasonably chew. Some recommendations (see also page 311)—on the future of the National Research Development Corporation, on the moving of basic research out of governmental research laboratories, on the functioning of the Advisory Council on Applied Research and Development, on the establishment of a Minister of Science and Technology, and on the extension of the customer-contractor principle into the Science Research Council (SRC) with the Department of Industry (DoI) as customer for the applied research—seem too hastily put together and based on too scanty evidence to be taken seriously. For instance on this last issue the committee has failed to consider that SRC, unlike the other research councils, supports little applied research in its own institutions, and that the proposal would, therefore, let the DoI (already well equipped with laboratories) choose to support or kill research projects in university laboratories—not, surely, the committee's intention.

It would be unfortunate, however, if the veritable deluge of half-worked-out proposals in the second half of the report were allowed to overshadow a valuable analysis, in the first half, of the development of post-war governmental support for science and technology education. It discusses the failures of new institutions and institutions with new names to convince bright students in large numbers that industry offered exciting

prospects—a failure compounded by industry's own inability to project itself as a place where highly qualified scientists and technologists would reach the top. The report echoes a DoI assessment that 'the overall trend is a decline in the numbers and quality of qualified scientists and engineers and of supporting staff in key areas of manufacturing'.

Status and motivation seem to emerge as the villains of the piece. Young people do not see engineering as a worthy profession in which to exercise intellectual skills; as a result there is too little understanding of what industry in all its complexity is about, or willingness to participate wholeheartedly amongst those 'forced' into it. The Select Committee, however, having inveighed against 'the distressing habit of attempting to bestow status (on academic institutions) by changing names', proceeds to propose as one recommendation that Imperial College, UMIST, University of Strathclyde and some former Colleges of Advanced Technology should be labelled SISTERS (Special Institutions for Scientific and Technological Education and Research). This is a revival of a 1963 idea to give technology greater prominence. The Rector of Imperial College will no doubt be mildly surprised to find that the committee propose that applied science and engineering at Cambridge be also made into a SISTER 'to ensure the high status of SISTERS is recognised by the academic community'.

The SISTER idea, unfortunately, is as poorly worked out as most of the committee's other ideas. To issue these institutions with revised charters limiting their functions to training and research in engineering and applied sciences would be to block all the fertile, increasingly necessary and in Britain often poorly developed cross-linkages into pure science, mathematics and economics. A dull narrow-minded product you'd get.

And yet the committee do at times get near to the centre of the problem: from early on in education the claims of industry and engineering are nothing like clearly enough presented. How many schools ensure that their pupils see a cross-section of industrial environments? How many industries make a serious attempt to get through to undergraduates, even to the extent of using them in vacations? The claims of an academic life are constantly being impressed on youngsters by their educational environment. Very often their only sight of industry before graduating is of strike picket lines on television news. There are some cautious ventures going ahead in this direction of mutual understanding, but it is up to the DoI, the Department of Education and Science and the Confederation of British Industry to stimulate much more. □

Stocks and shares

Questions about fish stocks lie behind Europe's fishing limits debate. **D. H. Cushing** discusses the state of stocks in the North-East Atlantic

THE conservation of fish stocks in the North-East Atlantic (between Cape Farewell and Gibraltar) started with the Overfishing Convention of 1946 which prescribed minimum landing sizes for demersal fishes in the ports and minimum mesh size in the trawl cod ends at sea. The Convention was activated in the Permanent Commission in 1953 which itself was replaced by the North-East Atlantic Fisheries Commission (NEAFC) in 1964 in order to acquire the power to regulate herring stocks as well as demersal ones. Sixteen nations have adhered to it voluntarily to conserve fish stocks internationally. In the last three years the Third Law of the Sea Conference has established a quite different trend towards coastal state management.

The present object of conservation is the maximum sustained yield (MSY) in weight. Men dispute whether it is a proper objective and propose others of various forms. In the North-East Atlantic, however, most stocks are overexploited and fishing effort should be reduced to obtain the MSY. This means that fewer ships at less cost would gain a greater catch and the average catch of each vessel or catch per unit of effort would be considerably increased. In his book *The Fish Gate* (Faber, London; 1943), Michael Graham named this principle the Great Law of Fishing.

The major stocks taken by fishermen in the North-East Atlantic comprise the cod-like fishes (cod, haddock, whiting and saithe), the flatfish (plaice and sole) and the pelagic species (herring, sprat and mackerel). The stocks are estimated by natural regions such as the North Sea, Irish Sea, Barents Sea and so on, between which exchange of individuals is usually low. The state of the stocks by species is summarised in the accompanying table; they are given by region (such as the North Sea) and are classed in four groups according to the reduction in fishing effort needed to obtain the MSY.

There are three stocks at or approaching the MSY with present measures: North Sea plaice, North Sea whiting and the cod in the Barents Sea. A slight restraint is required in five stocks: West Scotland herring, Iceland saithe, Faroe haddock and West Scotland cod and haddock. Eight stocks would be brought to the MSY

with moderately reduced fishing effort: Faroe cod, saithe in the North Sea and in the North-East Arctic, and both flatfish species in the Irish Sea, Bristol Channel and the English Channel. Unfortunately, there are fourteen stocks in need of heavy reduction in fishing effort: cod in the North Sea, Irish Sea and Bristol Channel, haddock in the North-East Arctic, North Sea, Irish Sea and Bristol Channel, whiting in the Irish Sea and Bristol Channel, sole in the North Sea and Irish Sea and herring in the North Sea and Irish Sea. The state of sprat and mackerel stocks in the North Sea and of mackerel stocks in the Western Approaches is uncertain.

Three reasons

There are three reasons why, after twenty years, most fish stocks in the North-East Atlantic remain over-exploited. The first concerns a limit in mesh regulation. The impact of an increase in fishing effort on a single species can be lessened to some degree by enlarged meshes in the trawl cod ends, but in a mixed fishery the meshes are fitted to the smallest fish species and any increase in fishing effort on the larger animals cannot be accommodated in this way. In the North Sea, mesh regulation was designed mostly for soles and haddock but the benefit for larger species like cod and plaice was less. In the North Sea and elsewhere in the North Atlantic, minimum mesh sizes were agreed by the end of the

Quota problems go deep in Denmark ...

1950s. But during the 1960s a considerable increase in fishing effort occurred all throughout these regions. In the International Commission for North-West Atlantic Fisheries (ICNAF), quotas were introduced in 1970 and in NEAFC in 1974. From North-West Atlantic experience, quotas stabilise fishing and prevent further expansion.

The collapse of herring fisheries throughout the North-East Atlantic illustrates the second reason for over-exploitation. The Downs stock, exploited by the East Anglian fishery, failed in the late 1950s, followed by other stocks in the North Sea; when NEAFC took power to regulate herring fisheries it did not succeed in doing so. When the Norwegian fishery on the Atlanto-Scandian herring stock collapsed in 1967, no action was taken. A contributory but minor cause of failure was the mistaken belief that fishermen must take fewer herring than the whales,

State of the stocks in the North-East Atlantic: reduction in fishing needed to obtain MSY

	None	Slight	Moderate	Heavy
Cod	North-East Arctic ¹	W. Scotland	Faroe	North Sea Irish Sea Bristol Channel
Haddock		Faroe W. Scotland		North-East Arctic North Sea Irish Sea Bristol Channel

Plaice	North Sea		Irish Sea Bristol Channel English Channel	
Sole			Bristol Channel English Channel	North Sea Irish Sea
Herring		W. Scotland		North Sea Irish Sea Celtic Sea

D. H. Cushing is Deputy Director of the Fisheries Laboratory, Lowestoft, UK.

¹At the present pattern of exploitation.

dogfish, cod and gannets that driftnetmen saw round their nets.

The major cause was the scientific dogma that fishing could never reduce the magnitude of the incoming year classes. Today we distinguish growth overfishing from recruitment overfishing. In growth overfishing the loss in numbers is greater than need be to give the maximum yield from the growth of individuals, and it is no accident that such individuals grow by an order of magnitude during their adult lives. In recruitment overfishing (often in herring-like fishes that grow little during their adult lives) the magnitude of the incoming year classes is reduced by fishing—an interference with breeding, as the fishermen used to say. The collapse of the herring stocks in the North-East Atlantic has been due to recruitment overfishing.

One of the difficulties was the high variability of recruitment; the dependence of recruitment on parent stock looked like a scatter diagram and sometimes the true relationships were masked. Indeed the belief that recruitment was independent of parent stock was mistakenly reinforced. The important conclusion, however, is that the overexploitation of the herring fisheries in the North-East Atlantic was less due to institutional failure than to the inability of scientists to understand the problems they faced. It remains true that the failure of NEAFC to take prompt and effective action was due in part to the difficulties of agreeing upon measures which would necessarily severely restrict the fisheries economies of some member states.

Considerable overexploitation

The development of industrial fisheries for fish meal in the North Sea has caused considerable overexploitation indirectly. During the 1960s herring were caught for fish meal on their spawning grounds and the trawlers were allowed to take 10% by-catch of those protected species which gathered to eat the herring spawn on the sea bed. Today more than two million tons of fish are taken from the North Sea for fish meal and the by-catches of protected species can be considerable. The sandeel fishery is 'clean' and little else but sandeels is caught. In the fishery for Norway pout (which are very small gadoids) in the northern North Sea, however, small haddock and whiting are caught in large numbers. In some years more than 100,000 tons of small haddock have been turned into fish meal, and in 1976 75,000 tons of small whiting were caught for the same purpose.

Norway pout are caught with small-meshed nets, legal under NEAFC rules, provided that the catch of under-sized protected species is less than 10%;

the total catch of Norway pout in 1975 exceeded 800,000 tons. The real difficulty is that fishermen exploiting adult gadoids for human consumption must not land fish below the minimum landing size and must discard them at sea, whereas fish meal fishermen can land large quantities of them; the large industrial fleets are seen everywhere in the North Sea and the traditional fishermen for human consumption see the small gadoids being taken which they themselves have to discard. Further, a rough calculation shows that 300,000 tons of Norway pout for fish meal are less valuable than 20,000 tons of haddock, had they been allowed to grow into the adult fishery.

After two decades of recruitment overfishing, the remaining herring stocks in the North Sea need drastic conservation measures. This need has at last been recognised by the industrial fishing nations who have agreed to a ban on all directed fishing for herring in the North Sea. But juvenile herring are caught in the industrial fishery for sprats; in 1975, about 600,000 tons of sprats were taken and the by-catch of small herring in the Danish catches was substantial. In other words, the industrial fishery for sprats not only prevents any chance of recovery of herring stocks, it also hastens the chance of extinction. A fair proportion of the world's catch of fish ends as fishmeal because of the high demand for it, and many industrial fisheries, like that for capelin in the Barents Sea or for anchoveta off Peru, exploit resources that cannot be used at all for human consumption. The problem peculiar to the North Sea is the conflict in use between fisheries for industrial purposes and those for protected species.

The three sources of overexploitation were recruitment overfishing, the conflict between fisheries for industrial species and those for protected species,

and the increase in fishing effort in ships, fishermen and gears. The herring and sole stocks in the North Sea are in danger from recruitment overfishing, but the problem has been recognised and steps are being taken in the scientific working groups to resolve it, even if the herring problem has not yet been solved in the Commission itself. The problems of the industrial fisheries are more difficult because of the large investment in ships and processing equipment in Denmark. Possible solutions include the diversion of such fleets on to stocks which would yield no by-catch of protected species, or to establish areas and seasons in the Norway pout and sprat fisheries when the by-catches of protected species are reduced to tolerable levels. The problem must be solved because it is hard to persuade the non-industrial fishermen to accept quotas or effort reduction when the industrial fleets are allowed to catch small gadoids and small herring.

The table shows that fishing effort should be extensively reduced throughout the North-East Atlantic. The introduction of quotas in 1975 has stabilised fishing effort; in ICNAF with a longer experience of quotas since 1970, an effort restraint was also introduced in 1976. The effort exerted on all the stocks on the right half of the table is much too great, which means that fleets in the North Atlantic will have to be reduced to some degree. There are few stocks left unexploited, but one is large, that of blue whiting off the west coast of the British Isles. Stocks are estimated at about 8–15 million tons and the potential catches could be large, but the exploitation has hardly started. Although some existing vessels could be used to catch the blue whiting, it remains the case that fishing on the great majority of other stocks in the North-East Atlantic must be reduced, in some cases drastically. □

... but overfishing problems go deeper

400 GeV . . . and beyond

Experiments begin soon on the 400-GeV Super Proton Synchrotron (SPS) at CERN, Geneva.

David Davies has been visiting the laboratory

SPS comes on line within budget and on schedule. After six years of awaiting the complicated multinational approval, and a further five of building an accelerator of radius 1.2 km which circles some 40 metres below ground, the physics starts in earnest in early December when the first high-energy particles are fed to a whole array of experiments. Major construction still continues, as the plans are for two completely separate experimental areas, only one of which is yet finished. But already questions are being asked: what do we build next?

CERN started life with a 600 MeV synchrocyclotron (SC) commissioned in 1957 and still in use. In 1959 a 28-GeV proton synchrotron (PS), fed successively by a 550-KeV electrostatic generator and a 50-MeV linear accelerator, was added. Although there is still an active physics programme on the PS, it also serves to feed the two other machines—the intersecting storage rings (ISR) and the SPS. ISR was completed in 1971, and comprises two rings of diameter 300 metres in which 28 GeV protons can travel for up to 40 hours in opposite directions crossing over and colliding at eight equally spaced positions—at six of which experiments are sited. The performance of the ISR in terms of storage current and luminosity is continually improving, and plans for its use well into the 1980s are being discussed at present (see page 314).

The advantage of machines in which beams travelling in opposite directions collide is that almost all the energy is available for particle production: SPEAR at Stanford and the projected PETRA at Hamburg are further examples, in which electrons and positrons are ranged against each other. In accelerators which bombard stationary targets, a large fraction of the energy goes in recoil of the target

particles. On the other hand, storage rings are restricted to a much smaller range of experiments—in other accelerators the primary beam is very often converted at a target to secondary beams of completely different particles.

The protons for the SPS are peeled off the PS in a continuous ribbon which eventually fills ten-elevenths of the SPS's seven-kilometre circumference. Once in the ring the 10^{13} protons encounter the magnetic field both of dipoles (which bend the protons in a horizontal plane) and quadrupoles (which keep the beam focused). There are 744 dipoles (peak field 1.4 Teslas) and 216 quadrupoles and the mean power consumption is 34 MW. The vacuum is 10^{-7} Torr. Acceleration of protons occurs at only one point on the ring, in a straight stretch of 40 metres where there are two radio-frequency cavities. Each journey through this section adds about 2.5 MeV to the protons' energy. After 150,000 circuits, which take 3.7 seconds, the protons are up to an energy of 400 GeV and ready to be ejected into either of the experimental areas, West or North. West Area is the first to be completed, North follows early in 1978.

The proton ribbon can either be extracted all in one turn or can be progressively peeled off over a period of up to a second. Bubble chamber experiments tend to need the short burst, electronic counter experiments the longer time. The beam can be used in the West Area in three ways:

- It can be directed on to an underground target at up to 40 GeV to produce pions and kaons which decay within 430 metres of their journey to the surface into muons and neutrinos. The muons are absorbed in steel and earth and the beam as it reaches the surface is solely of neutrinos which pass through the Big European Bubble Chamber (BEBC), two counter experi-

ments and the heavy-liquid bubble chamber Gargamelle.

- The protons can be directed to a second underground target to produce 75-GeV kaons or 110-GeV antiprotons which run into BEBC.

- The beam can be brought to the surface and split into three on entering the West Hall. Three targets are available to feed the twelve separate experiments set up in the West Hall with secondary beams of up to 150 GeV. The dimensions of the building—which existed prior to the SPS—preclude using higher energies; the North Area will be custom built for 400 GeV.

Why, it may be asked, has CERN built a 400-GeV proton accelerator when the Fermilab at Batavia, Illinois, installed a comparable machine more than four years ago—is it not needless duplication? The answer is complex and depends as much on subjective opinion as objective fact. But the list of SPS experiments approved at CERN gives some idea of the differences. Most striking are the number of neutrino experiments—13 out of 28. These take advantage of both the extremely high event rate anticipated from the neutrino beam-line and the excellent bubble chamber facilities. A second unique feature of CERN is the hyperon beam-line, yielding Ξ and Σ particles; an experiment on the decay characteristics of these particles will be watched with interest. A third will be the muon facility in the North Area.

It is also a mark of CERN's distinctive character that although roughly half of all experiments planned on the SPS are devoted to the "new physics"—hunts for J/ψ , intermediate vector bosons (maybe!), heavy leptons and charm—the other half tend to be "spectroscopic" experiments in the realms of "normal physics", painstakingly filling in gaps in knowledge without spectacular expectations.

Those who have worked in both Fermilab and CERN comment on the difference in style—Fermilab has a lot of flair, is able to latch on very quickly to new ideas, is vulnerable to failures (the magnets break down with

depressing regularity); CERN is more bureaucratic in its planning of experiments, is less prone to serendipity and yet runs so consistently well (SPS is expected to be extremely reliable) that much excellent definitive work can be done. As one physicist put it "at Fermilab you practically bring your experiments in cardboard boxes and stick them under tarpaulins; here look at the huge echoing halls and the gold-plated equipment!"

One of the problems that CERN is facing is the growing reliance of the high-energy physics community on one central facility as national facilities are tapered off. An exception is in Germany, where many reckon PETRA will produce some very exciting physics, and again will undoubtedly attract an international clientele; but otherwise there is nowhere else to go. Maybe the average number working on an experiment, which is 6 on the SC, 12 on the PS, 18 on the ISR and 25 on the SPS, reflects in part an increased complexity of experiment. But some believe that there are too many working on the SPS and that the quality of experience both for graduate students and research worker suffers accordingly. Another concern, raised first by Professor Jentschke last year when he was director of CERN's Laboratory I, is that very few physicists from CERN's smaller member states are finding their way into the teams for the SPS.

There is, on the other hand, some feeling around that CERN staff get a better deal than those who simply visit. The tax-free salaries are generous, to say the least, even allowing for the high cost of living in Geneva. And the cost of CERN's on-site services means that many (British, in particular) bring in their own technical staff.

Not surprisingly, there is a little apprehension at the moment at what financial adjustments the United Kingdom may try and negotiate at CERN's December Council. Dr J. B. Adams, the Director-General, is phlegmatic as always—"last year the Germans had some difficulties, the year before it was the French; these things come and go". But the real question is not a short term one. It is whether over the next five or ten years the nations contributing not only to CERN but also to other major accelerators are going to sustain their support for high-energy physics.

Within CERN itself there are already ideas circulating for new machines. The tunnelling for the SPS cost a relatively small fraction of the total bill, and some would like to see the SPS ultimately acquire an intersecting ring for proton/proton or even proton/antiproton studies. Such discussions,

Looking towards West Area from SPS

SPS plan, showing link with PS and experimental areas

however, are often coloured by a feeling that since the weak and electromagnetic interactions seem to be more fruitful sources of new states than strong interactions, a CERN venture into an electron machine might be a good next step. The European Committee for Future Accelerators has had a working party look at the physics potential of a 100-100 GeV electron-positron storage ring.

Fermilab, meanwhile, is exploring the possibilities of superconducting magnets to push its peak energy up to 1,000 GeV. The intellectual drive to get up to this level is that the postulated carrier of the weak force, the intermediate boson, probably has a mass so high (at least 37 GeV) that 1,000 GeV protons would be needed to unearth it. The prize from this could be unification of theories of weak and electromagnetic forces. CERN initially planned superconducting magnets in the SPS but eventually dropped back

to conventional ones because the technology was not far enough advanced.

At the same time Soviet physicists are looking to a 2,000 GeV proton synchrotron at the Institute of High Energy Physics, Serpukhov, as the next step from their 76-GeV synchrotron. Again, superconducting magnets are envisaged, to deliver the fields of up to 5 Teslas. Plans also include the simultaneous construction of a 20-GeV electron synchrotron with the capacity for proton-electron collisions.

It seems that plans for the next generation of machines are too far advanced in the United States and the Soviet Union for there to be any possibility of global collaboration. Attention has therefore turned to the idea of the next accelerator-but-one being a truly world machine, if only because a multi-billion-dollar price label is bound to be attached to it. A proton synchrotron at more than 10,000 GeV is a possible. But this is up to the politicians. □

USA

Where lies the test?

The Food and Drug Administration last week issued a set of regulations designed to help combat a growing scandal over drug testing in the United States. Colin Norman reports from Washington

A RELATIVELY unremarkable scientific paper, published early in 1972, has touched off a major scandal over the testing and regulation of drugs in the United States. It has led to allegations that some drug companies have conducted sloppy animal tests, faked results and presented misleading toxicity reports to the federal government—allegations which call into question the integrity of key parts of the drug regulation process and cast doubt on the safety of some products.

The allegations are so serious that the Food and Drug Administration (FDA) has already investigated the testing procedures and test reports of a few companies, and it is about to launch an unprecedented inquiry into the work of dozens of others. On the basis of what it has turned up so far, FDA last week issued a bulky set of regulations which essentially instruct the drug industry how to conduct animal tests and warn that drugs could be pulled off the market if it is subsequently discovered that misleading reports on them have been filed with FDA. The objective of the proposed new regulations, an FDA official said last week, is "to make sure that drug companies compete with each other on the quality of their professional work rather than on their level of cost-cutting".

The concern over the quality of drug testing was triggered by a study published in the *Journal of the National Cancer Institute* by Mario Rustia and Philippe Shubik of the Eppley Research Institute. The study indicated that a commonly prescribed drug, known as Flagyl, increases the incidence of pulmonary and lymphoid tumours in mice. The paper raised eyebrows in FDA because the agency had in its files reports of two studies submitted by the drug's manufacturer, G. D. Searle and Co., which claimed to show that Flagyl is not carcinogenic in rats.

A thorough check of Searle's study was then conducted by Adrian Gross, an FDA scientist. Gross concluded that Searle's study did indeed show evidence of carcinogenicity, but the company's report didn't reflect all the data. FDA officials took the matter up

with Searle, and two years later the company re-submitted its report. This time, Gross said in an interview last week, the summary agreed with the data, which would have been fine except that it was the data, not the summary, which had been altered. That finding prompted FDA to conduct a full-scale investigation into Searle's testing and reporting on several products. It was probably the most thorough federal investigation ever conducted of a drug company's scientific activities and it turned up some very disquieting findings.

The official report of the FDA investigation is among the most outspokenly critical federal documents that one could read. It states:

We have uncovered serious deficiencies in Searle's operations and practices which undermine the basis for reliance on Searle's integrity in conducting high quality animal research to accurately determine or characterise the toxic potential of its products . . . Searle has not submitted all the facts of experiments to FDA, retaining unto itself the unpermitted option of filtering, interpreting, and not submitting information which we would consider material to the safety evaluation of the product. Some of our findings suggest an attitude of disregard for FDA's mission of protection of the public health by selectively reporting the results of studies in a manner which allays the concerns of and questions of an FDA reviewer.

The task force which conducted the investigation recommended that the matter be turned over to the Justice Department, and that a grand jury be called to look into possible violation of the law. An FDA spokesman said last week that no grand jury investigation has yet been started, however. It should be noted that Searle's chief executive officer, Daniel Searle, acknowledged in Congressional testimony earlier this year that some "human errors" had occurred but he maintained that the FDA inquiry had found no evidence of fraud or misrepresentation by Searle personnel.

Whatever the outcome of the investigation, the Searle episode raises some very disturbing questions. FDA regulation of drugs and food additives is based largely on safety data submitted by the manufacturer of proposed new products. Thus, if manufacturers' test reports are unreliable, for any reason, much of the basis for FDA's regulatory actions could be open to doubt. And animal tests, it should be noted, are particularly important since they provide the chief means of identifying whether or not new products may have potential long-

term problems, such as carcinogenicity, teratogenicity, and mutagenicity—problems which don't show up in clinical trials on humans.

Because of the serious implications if FDA is regulating drugs and food additives on the basis of unreliable data, Congress earlier this year added \$16.4 million to the agency's budget for an investigation to determine whether the problems uncovered at Searle are widespread in the industry. Senator Edward Kennedy, who was instrumental in securing the extra funds and in bringing the matter to public attention, noted last January that "if data are proven false and misleading, then the regulatory decisions may be tragically wrong".

FDA's investigation is about to get under way in earnest. During the next three months, inspectors from the agency will look into testing procedures and facilities of about 40 drug companies and independent testing laboratories. But FDA has already gathered alarming evidence that the problems are not limited to Searle.

Last week, the agency proposed a set of so-called Good Laboratory Practice (GLP) regulations which spell out standards which FDA will require for animal tests of drugs and food additives. In a preamble to the proposed regulations, FDA Commissioner Alexander M. Schmidt states that a number of recent investigations conducted by FDA in cases where the agency had reason to be suspicious of test reports "have identified significant problems in the manner in which nonclinical laboratory studies are being performed". The deficiencies, Schmidt said, were uncovered during inspections of "major pharmaceutical firms, inspections of several private contract testing facilities, and internal reviews of toxicity studies of color additives conducted by FDA".

The problems included the following:

- "Pathology reports submitted to the agency were inconsistent with the original autopsy records".
- "Microscopic tissue slides were conducted by more than one pathologist, each of whom came to different conclusions, yet only the conclusions favourable to the drug were submitted to the agency".
- No records were kept for any individual animal in one long-term feeding study, "despite the fact that the records were required for proper analysis of the study and were represented to the agency to exist".
- "Animals were recorded as normal for a variety of factors, including

awareness, appearance, appetite, and thirst, when in fact the animals were dead".

- "Drugs were administered to animals in a manner which made it impossible to determine how much, if any, of the required dosage was actually ingested by the animal".

- In one toxicity study, "gross changes of tissue began to appear, yet management was not made aware of these alarming changes for approximately 4 to 8 months.

- In a study done by an independent testing laboratory, FDA was told that animal tissue samples had been examined when a review of laboratory records indicates that the tissue samples had never even been collected.

Such alarming, and possible fraudu-

lent, incidents are supposed to be stopped, or at least made more difficult, by FDA's proposed GLP regulations. But the regulations would in fact not be unduly burdensome. They set standards for the training of laboratory personnel, the quality of facilities and equipment, the handling of test animals, and the keeping and reporting of test data. They also specify that a Quality Assurance Unit must be established in each facility to ensure that the GLP regulations are followed. In short, the proposed standards are no more strict than those which should already be in force in any self-respecting facility.

Perhaps the most important aspect of the proposed regulations is that they spell out a number of sanctions which FDA could invoke if violations of the GLP standards are encountered. The ultimate sanction would be to

remove a product from the market if FDA had approved it on the basis of test reports subsequently found to be false or misleading. Another proposed sanction would be to disqualify a test facility as a source of information in support of a future marketing permit. Such action would be tantamount to shutting down a contract laboratory which makes its living from conducting toxicity tests for the drug industry. Finally, FDA points out that deliberate faking or misleading reporting of test results could be subject to criminal prosecution.

The proposed GLP regulations are open for comment for 120 days and FDA plans to conduct public hearings on them early next year. By that time, the results of the inspection effort should be available to provide an indication of the scope of the problem. □

SEVESO

The problems deepen

Italian authorities are now pondering how to clean up an area near Seveso in northern Italy, following an accident last July which released large quantities of dioxin into the environment. Some important new information bearing on the problem has surfaced in the United States. Colin Norman reports

DIOXIN in the soil of the most heavily contaminated area near Seveso can be expected to take up to 14 years to break down to levels at which the compound can no longer be detected. But there is unlikely to be much, if any, movement of dioxin in the soil, and the contamination will probably be confined to the upper 12 inches for a long time.

Those conclusions have emerged from an analysis of previously undisclosed studies conducted by the US Air Force, and from information gathered as a result of a bizarre dioxin contamination incident in Missouri in the early 1970s. The studies were ferreted out and analysed by Barry Commoner and Robert E. Scott, researchers at the Center for the Biology of Natural Systems at Washington University. Scott and Commoner have sent their conclusions to authorities investigating the Seveso disaster.

The Air Force studies, which were released to Commoner on October 28, involved soil tests with military herbicides contaminated with dioxin, left over from the Vietnam war. They involved heavy spraying of plots of land in Utah, Kansas and Florida, and subsequent monitoring of dioxin levels in

the soil. Commoner and Scott conclude from the studies that the likely half-life for breakdown of dioxin in the soil at Seveso is about 250 days, a rate which suggests that it would take about 14 years for contamination to disappear from the most heavily affected area (Zone A) and about seven years to degrade to undetectable levels (about 10 parts per trillion) in the surrounding zone (Zone B).

But, in spite of an annual rainfall of about 60 inches in Florida, the Air Force study indicated that dioxin in the test plot there did not migrate in the soil. That finding is particularly important because there has been recent heavy rainfall in Seveso which has led to worries that the dioxin may have been washed through the soil into the groundwater. "It may be expected that the TCDD present in the upper layers of the soil at Seveso will probably not migrate downward significantly, in spite of the heavy rainfall", Commoner and Scott conclude. Those observations lead them to note that if the soil at Seveso is left in place, contamination is unlikely to spread, but alternatively if the upper layers of soil are stripped off and replaced with fresh soil, any dioxin left in the lower layers would not be expected to migrate to the surface.

The Air Force study has also yielded information on the effects of low levels of dioxin on wildlife. Samples of wildlife around the Florida test plot indicated significant bioaccumulation of the contaminant, and there was also a marked drop in the fertility of beech mice in the area. The observations lead

Commoner and Scott to conclude that wildlife at Seveso will be affected unless soil concentrations can be reduced to about 500 parts per trillion, compared with the average concentration of about 10 parts per million in Zone A. Such a reduction, they note, "could be most rapidly achieved by removing the upper layer of soil and replacing it with uncontaminated soil".

The other information analysed by Commoner and Scott was derived from observations following an incident in which waste oil heavily contaminated with dioxin was sprayed on the ground in four places in Missouri in May and June, 1971. The dioxin contamination was unknown at the time.

One application involved spraying the ground in a horse arena shortly before a show to keep down dust. Hundreds of birds and several horses died as a result of exposure to dioxin and three months later a young girl who had been playing in the arena was admitted to hospital with symptoms ranging from nosebleeds and headaches to severe disuria and hematuria. In October, four months after the spraying, between six and eight inches of topsoil was removed from the area and replaced with fresh soil, but deaths of horses, cats and other wildlife persisted. In April, 1974, four years after the accident, a further six inches of soil was removed, whereupon the toxic effects disappeared.

The original contamination in the arena was reckoned to be about 30 parts per million, a level similar to that in Zone A, and thus the observations compiled by Commoner and Scott are directly relevant to the Seveso investigation.

Commoner and Scott conducted

their study under the auspices of the Scientists Institute for Public Information.

● **Alastair Hay adds:** At the time of the Seveso explosion, 150 women resident in the area were in the first trimester of pregnancy. Most of the women applied for a therapeutic abortion when informed of the teratogenic properties of dioxin. Following examination by health officials of 730 pregnant women formerly resident in the contaminated area, only 29 have had the operation. The fetuses removed from these women are currently being examined for any signs of abnormality.

Professor Francesco Cefis of the *Istituto Clinico di Perfezionamento* in Milan, and Professor Alfred Gropp, Head of the Pathology Department of Lübeck Medical School in Germany, are in charge of the investigations. Neither would comment last week on the results of their observations so far. Only five of the 29 fetuses have been examined and Professor Cefis estimated that it would take another two months to complete the study. By then women who were in the earlier stages of pregnancy in July will be six or seven months pregnant—too late for an abortion to be performed.

The rate of spontaneous abortions in the Seveso area is reported to have increased to twice the Italian national average since July. The rate of miscarriage was reported to have increased similarly in Vietnam following spraying with the herbicide 2,4,5-T. Both the trichlorophenol discharged at Seveso and the 2,4,5-T used in Vietnam contained dioxin. The Vietnamese authorities maintain that dioxin was responsible for the miscarriages

Towards anticipating disaster

In Britain last week the Insurance Technical Bureau (ITB), which leading insurance groups established in 1972 as a non-profit making organisation with "technical expertise in the field of industrial loss prevention", demonstrated 'Anticipator', a new system designed to alert managers of chemical plants to potential hazards in their site installations.

One of the recommendations made by the 1974 Court of Inquiry into the Flixborough disaster was that some form of recorder should be made available to monitor operating conditions in industrial installations. This would perform a function similar to that of the 'black box' flight recorder in aircraft. 'Anticipator' is a sophisticated monitoring system with its own computer which will register information about pressure, temperature, flow rates,

gas leaks, vibrations and other factors relevant to the safe operation of a chemical plant. It can be pre-programmed to record only data which fall outside normal working parameters, making interpretation a relatively simple process.

The designers argue that incidents usually "cast their shadows before them", and feel certain that Anticipator would have prevented accidents such as those at Flixborough and Seveso. With the primary research and development work now completed at a total cost of £50,000, the ITB propose to find a commercial concern to develop the system for marketing. The trouble is, the biggest firms do their own monitoring, and the smaller ones may not be able to afford the new device.

Alastair Hay

which they recorded.

Meanwhile, the scientific commission responsible for formulating a policy to decontaminate the area containing dioxin has still not agreed upon methods to be employed. Frustration at the apparent inactivity has been expressed both by experts anxious to begin the work of decontamination, and by former residents of the area who last week tore down protective fences in protest at the delay.

The work of the commission has been hampered by the disagreement among experts concerning the amount of dioxin to be dealt with. Dr Donald Lee of the Plant Pathology Laboratory at Harpenden, UK, suggests that 130 kg of dioxin was released in the explosion, and Professor Samuel Ep-

stein of the University of Illinois, considers the figure of 300 lb of dioxin to be "about right". But a group of chemical engineers invited by the commission to submit a programme for decontamination estimate that 1-3 kg of dioxin was released, a figure based on results obtained from a simulation of the explosion.

The two top officials of ICMESA, who after being arrested and charged with culpably causing a disaster were released on bail to supervise decontamination work within the ICMESA plant, have since been rearrested and criminal proceedings have begun. The criminal prosecution will be conducted at the same time as the civil proceedings brought against Hoffman-La Roche, ICMESA's owners, by the Italian authorities. □

EEC

Manoeuvring for agreement

The EEC's Council of Research Ministers met in Brussels last week to discuss once again the Joint European Torus (JET), the Community's fusion project, and the research programme for the Community's Joint Research Centre (JRC). Chris Sherwell reports

So near and yet so far. The EEC now looks sufficiently close to agreement on the site for JET that the small step the Council of Research Ministers took at their meeting last week may in retrospect come to look like a giant leap for the Community. But because there is still ample scope for more than one hitch, the prospect could be as much for a leap backwards as a leap for-

wards.

On paper the progress that everyone is keen to say really did occur in Brussels certainly looks very slight. The Council reached just one firm decision with any consequence in terms of action or expenditure. This was that the Community's fusion programme, which is undertaken by a number of associated laboratories in the member states but does not include JET, could go ahead for another four years.

To call that insignificant, though, is to reckon without the intricacies and nuances of Community deliberations. Until now there has been no agreement on expenditure for the full five years of the fusion programme. When the programme first came up for discussion

last December, Italy refused consent, saying she could not agree without a decision on a site for JET. She modified this position at a February Council meeting, allowing just one year's expenditure. In the view of one senior official in Brussels, therefore, the absence last week of continued further blocking of the programme from Italy means that the decision can be interpreted as a positive sign for JET.

What changed Italy's mind? The answer is to be found in the way the JET argument has developed. Italy's concern has always been principally over the fate of Ispra, one of the four establishments constituting the JRC—the others are in Germany, Belgium and the Netherlands, but Ispra is the largest with two-thirds of the JRC staff. By the last Council meeting in October it had become clear that progress on

JET might be possible if the Council would sanction in full the four-year (1977–1980) JRC research programme put up by the European Commission during the summer, much of which would go to Ispra.

The difficulty, however, was that Britain, France and Germany had made various demands for cuts in staff and expenditure on the proposed JRC programme. Germany was seeking cuts of less than 100 in staff, France was looking for cuts of around 200, and Britain had proposed a figure in excess of 300. Modifications in these demands was plainly necessary if there was to be any relaxation in the Italian demand for JET at Ispra—a demand which the Commission had itself backed on the grounds that a Community project should go to a Community centre.

The flexibility was evidently there, and the key development last week was a provisional agreement on these matters. Britain and France went to Brussels apparently prepared to pare back their demands to around 100—the number which it was thought could be lost through “natural wastage”—and eventually conceded along with Germany that the figure could be 80. This was the compromise proposal put up by the Commission after no agreement could be gained on the Commission's original compromise proposal of 50. It is damaging to Italy's hopes for Ispra inasmuch as the staff cuts, details of which obviously have to be finalised, are likely to fall most heavily on Ispra.

The agreement makes for a reduction in operating expenditure from 175 million units of account (mua) to 146 mua and so cuts the overall JRC budget for the four years to something like 346 mua. But there is a catch in all this: the agreement is conditional on

a suitable agreement being reached over JET. Thus, although the JRC research programme is at last final, little if anything can be done about it without further progress on the matter of the JET site—and on this there was little progress in Brussels.

What chinks of light there are, though, suggest that the matter is now delicately poised. Seven of the nine countries agreed last week that the site ought to be at a location with previous practical fusion and plasma physics experience. Significantly, it was France and Italy who thought this not to be relevant. France's proposed site, Cadarache, does not have fusion experience. Ispra has fusion experience and is not officially withdrawn, even though it now looks a less strong candidate with the provisional agreement on the JRC programme. The cases of both Culham in Britain and Garching in West Germany are strengthened by their experience.

The uncertainty is thus tangible. There are differences between France and the other countries on the degree of Euratom staffing that JET ought to have. But these are thought not to be insuperable. More importantly, the Council could not even agree last week on a procedure by which agreement might be reached. As a result, the Dutch chairman, Mr Brinkhorst, and the EEC Research Commissioner, Mr Brunner, are to tour the countries concerned to discuss the sites still further. If they determine that the basis for an agreement exists—the agreement when it comes will have to be unanimous—they will call for another Council meeting, provisionally scheduled for December 20.

The Community's fusion director, Mr Palumbo, has a few illusions about

that meeting, since if it takes place it would be the last one as far as JET was concerned. If it doesn't take place, he stresses, the whole project could be seriously endangered. Officials concerned with the JRC are somewhat more sanguine about the impact of a delay on the research programme, even though it is due to start in January. But the delay could be enormous. A new country takes the Council chair in January. That is Britain. And a new president takes over at the European Commission. He is from Britain. The latter change could well exacerbate any delay. Both changes could, in the present circumstances, make a difference to the outcome over JET.

No one, of course, is saying that the changes will help Culham win JET. But it was generally agreed last week that the choice had now narrowed substantially. In fact the case for Culham may well be strengthening. If Ispra is now discounted, the argument goes, that leaves Cadarache and Garching as Culham's competitors. And the rather sudden strength in the previously quietening voice for Cadarache can be discounted because it comes too late, because seven countries think experience is important and because Britain wouldn't wear it.

Garching can also be discounted, the argument goes on, because the Germans once again did not push strongly for it at last week's meeting, because it has the biggest fusion programme of the nine countries and plans its own large machine (AZTEC) anyway, and because it already has a Community research establishment. But if Germany does not get JET, what would it get? Well, speculate the cynics, watch out for a German filling the post of JET project director. □

BRITAIN

Changing the framework

A UK parliamentary committee last week published a 96-page report on university-industry relations. Chris Sherwell reports on the various institutional proposals of what could become a controversial document

WITH friends like the House of Commons Select Committee on Science and Technology, those amongst Britain's science community looking for a bit of stability in the country's science policy framework may not need enemies. For at the very time when the projected evolution of that framework seems virtually complete, the committee has published a wide-ranging report going beyond the narrowest confines of its

subject to offer proposals for further substantial changes.

The report is the result of written submissions and a score of public hearings initiated by the committee's Science Sub-committee. It follows an interim report on scientific research in British universities published in July 1975 and a second report released at the end of last year, and is “concerned with the purposes of the institutions of advanced scientific education and research”. The committee, clearly inspired by the idea that science policy should relate to the general social and economic objectives of the community, says it is essential “that we should be prepared to re-examine the organisation of science and scientific education in

terms of our current needs”.

Its recommendations regarding the framework within which British science policy is conducted may not throw the whole matter into the melting pot again. But in focusing directly on the country's capacity to conduct research and development they seem certain to fuel the arguments over whether an explanation of Britain's economic performance is to be found in the areas of innovation, investment and productivity, and hence also in the very platform of its science policy.

The most far-reaching recommendations are for the appointment of a junior minister in the Department of Education and Science (DES) with responsibility for science, for the transfer of funds from the Science Research Council (SRC) to the Department of Industry (DoI), for a review of the

relationship of basic and applied research in Britain, and for a possible new institution to replace the National Research Development Corporation (NRDC).

The proposal for a minister emerges from a discussion of education and training of engineers and applied scientists, for which the report argues most strongly. Among other things the committee also says the concept of Special Institutions for Scientific Education and Research (SISTERS) should be "revived and implemented", and urges the DoI and SRC to devote greater attention to the "teaching company" idea—a recommendation which post-dated by a couple of days an announcement of a £500,000 scheme for three such companies to improve university-industry links. But the idea of a Science Minister will look curious to many, and not just because it is an old idea that was dismissed when the present policy framework was worked out.

The minister, the report says, "should be principally concerned with scientific and technical education at all levels of the education system, and with the activities funded from the Science Budget". That seems unlikely to find much favour among those who relate the need for a minister to the amount of money he would handle, and still less likely if the biggest money-eater in the Science Budget, the SRC, ought according to the committee to have some of its funds transferred elsewhere.

The argument for that transfer—perhaps the most contentious proposal—is straightforward. The direction of a country's basic research, it goes, affects its capacity to do applied research which is geared to national needs. Traditional academic criteria directing basic research cannot guarantee that capacity, even with unlimited money; with declining funds, a research council system which uses such criteria is a luxury. Knowing this, the argument goes on, the research councils talk in terms of national needs and are put in an intolerable position; the SRC, whose support for applied research (unlike other research councils) is not subject to the ameliorating effects of the customer-contractor principle, suffers especially.

Thus, proclaims the report, "there is a good case for the transfer of a proportion of the Council's funds to the Department of Industry, which is the natural 'customer' department for the applied research supported by the SRC". The idea is to let the SRC take the decisions it is qualified to take, and not review research needs in terms of inadequately-defined national priorities. Those priorities should be determined by those responsible—the commissioning departments acting through their

ministers in Cabinet.

The proposal for a review of the relationship of basic and applied science is similarly related to the existing framework of science policy. In the three years up to April 1976 during which funds previously disposed of by research councils were transferred to the relevant departments under the customer-contractor arrangements, other organisational changes went ahead. Departments acquired chief scientists, and the emerging task of coordination between departments fell to an inter-departmental committee of chief scientists and permanent secretaries. The position of Chief Scientific Adviser to the government fell away, but the Cabinet's Central Policy Review Staff in turn had a chief scientist attached to it.

In addition another entirely new body was also created. Known as the Advisory Council for Applied Research and Development (ACARD), it was designed as the equivalent in applied research to the Advisory Board for the Research Councils (ABRC) in basic research; it is chaired by the Lord Privy Seal. Welcoming ACARD, the committee says it should "review the relationship between government-supported applied R&D and government-funded basic research as a matter of urgency". In particular it should "examine the operation of the customer-contractor relationship and of the ABRC to ensure that effective machinery exists for relating basic science policies to long term departmental R&D strategies". ACARD's reviews should be published, and the Lord Privy Seal ought also to make annual reports to parliament, the committee says. It does not consider whether ACARD is the appropriate body to conduct such examinations.

The committee claims it is not making sweeping recommendations for changes in the organisation of government R&D. Among its other proposals is one that the government undertake "a thorough review of the level and nature of the research undertaken in their own establishments" and attempt to transfer to universities and polytechnics "work of a more basic nature, not requiring major physical research facilities, wherever this is possible". Another is that encouragement be given, for example, to bringing higher education and industry into closer alignment; the committee says there is a good case for devising financial incentives "possibly in the form of generous tax allowances" to encourage companies to place research contracts with universities.

The most controversial points it makes in this area, though, are likely to be those concerning the NRDC. The committee says "urgent attention"

should be paid by the government to the "mis-match between the activities of the SRC and NRDC", and "urgent action" should be taken to correct it. It recommends a number of changes which, if implemented, would make the NRDC less concerned with producing a financial return from the results of research and more able to give advice and assistance. The functions it proposes for NRDC, says the Committee, may well be better performed "by a new institution without the accumulated scepticism and indifference which NRDC's policy and activities appear to have generated in some quarters"; as it is, the NRDC activities are "in no way conducive to encouraging the exploitation of academic research".

Last week the head of NRDC, comparatively unexcited by the report, said he would have been surprised if there hadn't been some adverse criticism, particularly as the committee provided an ideal forum for complaint. He happily acknowledged that there was some truth in the report's comments on NRDC but thought many of the criticisms were unjustified, adding that NRDC expenditure in relation to higher education institutions would have to be perhaps quadrupled if the right service was to be given, and more than a simple change in the NRDC's terms of reference was involved.

The SRC had not by the beginning of this week made any plans to issue a statement on the committee's report. Whatever the reaction to it inside universities and industry, it seems clear that its real impact will depend ultimately on how the Select Committee itself is viewed as an institution. The committee's members are hoping now for a parliamentary debate on the subject, which seems the only viable means by which its recommendations can be urged upon the government short of some positive response from outside. □

● A team of about 10 scientists would be adequate for British biological warfare research, a junior Defence Minister, Mr Gilbert, said in a parliamentary written reply last week. A reduction in military research in the Microbiological Research Establishment at Porton Down, Salisbury, had been on the cards since the announcement of a review of its spending in the March 1976 White Paper on Defence. Mr Gilbert's announcement means that the establishment's future depends on its civil work, at present under study by the government's Central Policy Review Staff and the National Institute for Biological Standards and Control, who hope to report before the end of the year. Up to one third of the establishment's running costs are currently met by revenue from its civil work.

Intermittent nerve conduction

from Shin-Ho Chung

ALMOST every axon in the central nervous system ramifies profusely before making synaptic contacts with its target cells. This terminal arborisation is formed by the axon bifurcating into branches, the branches into twigs, and the twigs into fine terminal filaments. A single axon entering the superior cervical ganglion, for example, establishes about 1,500 synapses with its post-synaptic neurones, and all of these contacts are believed to be activated by an impulse in the main axon. However, several recent studies have shown that not every impulse flowing down the main axon invades all of its terminals; instead, at each bifurcation some impulses are channelled into one branch and are prevented from invading the other. This process, known as 'intermittent nerve conduction', is incompatible with the classical idea of the axonal tree as a simple distributor of nerve impulses to a large number of the next-order neurones, and it invites further investigation.

Barron and Matthews (*J. Physiol. Lond.*, **85**, 75; 1935) first noticed the phenomenon of intermittent conduction in a class of sensory fibres in the cat, which enters the spinal cord and sends branches back to the skin through neighbouring dorsal roots. When monitored in a branch coming out of the cord, a steady stream of impulses entering the cord was found to be transformed into an intermittent series, with an alternating sequence of discharge and silence. The pattern of this conduction block depended on the frequency of discharge in the recording fibre as well as on the amount of neuronal activity in the neighbouring fibres; for example, when the spinal cord was active with ascending sensory discharges, the block became frequent and long-lasting. Barron and Matthews believed that this phenomenon of intermittent conduction was one of the mechanisms by which the central nervous system regulates the flow of impulse traffic and 'transforms

a simple sensory discharge into a sensation.' After the dorsal root reflex was described (Toennies, *J. Neurophysiol.*, **1**, 378; 1938), Barron and Matthews' observations were erroneously assumed to be a special instance of it, and, except for a few sporadic notes (Fuortes, *J. Physiol. Lond.*, **112**, 42p; 1950; Howland *et al.*, *J. Neurophysiol.*, **18**, 1; 1955), their very accurate and detailed descriptions were, in the main, ignored.

The phenomenon has now been re-examined in the simple nervous system of invertebrates, where the branching pattern of a single axon can be viewed under a microscope. In the crustacean leg or abdomen, for example, a single motor neurone branches many times in its intramuscular course, and the terminals of the two main branches innervate two separate groups of muscles (Bittner, *J. gen. Physiol.*, **51**, 731; 1968). When the main axon is stimulated at a low, steady frequency, impulses travel to both groups of muscles, but the junctional potential is large enough to cause contraction in only one of them. As the frequency of stimulation increases, the speed of propagation into the branch serving the contracting muscle becomes reduced as the impulse momentarily hesitates before invading it (Hatt and Smith, *J. Physiol. Lond.*, **259**, 367; 1976). The flow of impulses into this branch is then abruptly blocked, whereas the other branch continues to admit impulses and the muscle served by it begins to contract (Grossman *et al.*, *Brain Res.*, **64**, 379; 1973; Parnas, *J. Neurophysiol.*, **35**, 903; 1972). Hints of a similar phenomenon exist in the results of studies on a variety of other neurones such as the sensory afferent in the leech (Van Essen, *J. Physiol. Lond.*, **230**, 509; 1973) and the giant axon of the cockroach (Spira *et al.*, *J. Neurophysiol.*, **39**, 882; 1976; Castel *et al.*, *ibid.*, 900).

The mechanism by which the propagation of nerve impulses is blocked

is not thoroughly understood. There are several reasons for supposing that the conduction failure occurs at the point of branching or at the region where the geometry of the axon undergoes a sudden change. Ordinarily, the currents produced by an impulse travelling down an unbranched axon have about four times the magnitude necessary to ensure continuous invasion. At points of branching, the current from the parent axon is split between the daughter branches and, at the same time, must charge a larger capacitance. This causes not only an attenuation of the exciting current, but also a hesitation of the nerve impulse, allowing sodium inactivation to develop. Such a region with a low safety margin is likely to be most susceptible to a small shift in ionic environment, and accumulation of some ions in the extracellular space following repetitive stimulation may further reduce the safety margin so that the transmission of nerve impulses fails completely (Smith and Hatt, *J. Neurophysiol.*, **39**, 794; 1976; Spira *et al.*, *op. cit.*). Theoretical computations based on the Hodgkin-Huxley equations predict that the increased concentration of potassium in the extracellular space during repetitive firing will cause conduction failure at the region where the geometry of the axon undergoes a sudden constriction (Parnas *et al.*, *J. Neurophysiol.*, **39**, 909; 1976). This, however, is not the only condition which may bring about the conduction block. Prolonged hyperpolarisation of the axon (Van Essen, *op. cit.*), temporary anoxia (Krnjevic and Miledi, *J. Physiol. Lond.*, **149**, 1; 1959), or currents arising from activity of neighbouring fibres (Lettvin *et al.*, *Brain Behav. Evol.*, **3**, 72; 1970) may have the same effect.

Whatever the precise mechanism ultimately turns out to be, the finding that axonal trees do not faithfully convey impulses to their terminals will have several important implications in

neurobiology. If we accept the classical view of the axon as a passive distributor of impulses, then there appears to be a serious defect in its performance. In order to overcome this defect, the nervous system may form a large number of redundant connections so that intermittent failure of nerve conduction will not seriously hinder the processing of neural information. Alternatively, as Lettvin and his colleagues maintain (*Brain Behav. Evol.*, *op. cit.*: see also Waxman, *Brain Res.*, **47**, 269; 1972), the

axonal tree may act as a filter, regulating the flow of impulses into one or other branch, depending on the temporal pattern of firing. It is quite common for a single nerve to innervate more than one type of post-synaptic cell, and if the axon is capable of controlling one or the other, or both, through its firing pattern, as demonstrated in the crustacean motoneurone, then what appears to be a fatal defect of the bifurcating axon may turn out to be a very useful property in achieving an economy in neural organisation.

Mysteries of early dinosaur evolution

from Barry Cox

ALTHOUGH many pages have been written discussing the mystery of the extinction of the dinosaurs, almost as much uncertainty surrounds their origin—or origins. The large Mesozoic archosaurian reptiles known as dinosaurs belong to two separate groups, the Saurischia and the Ornithischia, which differ in such characters as the structure of the pelvic girdle and the possession of a prenatary bone (present only in ornithischians). A diversity of saurischians is known from the late Triassic, as are about six genera of ornithischians. But the relationships of the two groups to each other, or to the earlier Triassic archosaurians known as pseudosuchians, remain uncertain.

By the Early Jurassic, saurischians include at least two types. The small carnivores (or coelurosaurs) and the large carnivores (or carnosaurs) were both bipedal, and are both placed in a single group, the Theropoda. Late Triassic coelurosaurs are known, but no Triassic carnosaurs have yet been found. The other saurischian group, the Sauropoda, comprises the very large, quadrupedal, long-necked herbivores of the Jurassic and Cretaceous. Their Triassic ancestry runs back into an assemblage of quite large facultatively bipedal forms, the prosauropods, which include both herbivorous and carnivorous types. It is therefore at least possible that the coelurosaurs, the carnosaurs and the prosauropods all had quite separate origins from within the pseudosuchians. Various authors, such as Charig and Bonaparte, have suggested this, basing their views mainly on apparently divergent structural modifications of the ankle in these groups.

So far, at least, there has been less evidence of diversity in the Triassic ornithischians; only two, rather similar families are known. Smaller than most of the saurischians, their structure has

been less well known, but an article by Santa Luca, Crompton and Charig in this week's issue of *Nature* (page 324) provides a preliminary account of an exceptionally fine specimen from the very late Triassic of South Africa. This little bipedal, fast-running herbivore, *Heterodontosaurus*, had already developed a number of specialised features, such as the grasping hand and some degree of fusion of the bones of the ankle. Ornithischians, then, had also clearly been evolving and radiating for some time before the end of the Triassic.

If one now attempts to relate these two types of dinosaur to the Triassic pseudosuchians, there appears to be a puzzling overlap in time between the two groups, although possible evolutionary links between them obstinately refuse to appear. Though the pseudosuchians include large bipedal carnivores, the ornithosuchids of the Middle and Late Triassic, which have been suggested as ancestral to the carnosaurian dinosaurs (Walker, *Phil. Trans. R. Soc.*, **B248**, 53; 1964), this has since been denied by Bonaparte (*Coll. int. Cent. nat. Rech. sci.*, **218**, 485; 1975). The large Late Triassic quadrupedal pseudosuchian carnivores known as rauisuchids (or prestosuchids) have been nominated as the possible source of the saurischians, while the only pseudosuchian similar to the little ornithischian dinosaurs is the small bipedal genus *Euparkeria* of the Early Triassic.

The possible ancestors of the different types of dinosaurs are thus scattered through the Triassic, and the pseudosuchians persisted until the end of that Period. Throughout the Late Triassic, at least, a variety of pseudosuchians therefore coexisted with a variety of their presumed descendants, the dinosaurs, as has been pointed out by Sill (*Bull. Mus. comp. Zoo. Harv.*, **146**, 317; 1974). The perhaps multiple

evolution of dinosaur lineages therefore did not lead to the rapid ecological replacement of their pseudosuchian ancestors. These instead persisted, together with their relatives the semi-aquatic phytosaurs and the pig-like rooting aëosaurs, until the end of the Triassic, when all became extinct together—though no new ecological replacements for them appeared at that time.

So the poor palaeontologist searching for answers is therefore, in the origin of the dinosaurs, confronted with complexity where he hoped for simplicity, while in the replacement of the pseudosuchians by their varied offspring he meets a sudden (if delayed) simple event where he expected complexity! Today, the fashionable *deus ex machina* for explaining extinctions is continental drift, but even rising sea levels resulting from the beginning of the opening of the Atlantic in the Late Triassic seem unlikely to provide a solution to these puzzles. □

Future of the CERN intersecting storage rings

from M. G. Albrow

A Workshop on Future ISR Physics was held at CERN, Geneva on October 4–15, 1976.

In January 1971 two beams of high energy protons were trapped in the CERN Intersecting Storage Rings (ISR) and brought into head-on collision for the first time. This achievement enabled high energy physicists to study particle interactions, under well-controlled laboratory conditions, at energies otherwise accessible only with cosmic rays. The ISR beam energy ranges up to 31 GeV; an accelerator of 2,000 GeV would be needed to obtain the same effective collision energy using a particle beam on a stationary target. The present commissioning of the 400 GeV SPS accelerator at CERN, and plans at the Fermi National Accelerator Laboratory to construct a 1,000 GeV "Energy Doubler", have stimulated a re-evaluation of the role of the ISR in high energy physics. There is no doubt that the ISR has a unique position in terms of available collision energy; the question is whether that advantage is important enough to guarantee an exciting programme of physics for many years to come, and therefore to justify its continued operation in the present financial climate. A workshop, attended

by about 50 physicists from Europe and the United States, was recently held at CERN to discuss such questions and try to define a research programme for the ISR after the present generation of experiments, that is, into the next decade. Here I have attempted to summarise the most promising of the ideas considered.

The concept that the strongly-interacting particles (or hadrons) are composite objects containing more fundamental constituents, for example quarks and antiquarks, has achieved almost universal recognition over the past 12 years. All the known hadrons can be constructed from a basic set of four quarks q (up, down, strange and charmed) and their four antiquarks \bar{q} . The proton is supposed to contain three "valence" quarks (up, up and down) which determine its quantum numbers, as well as a sea of $q\bar{q}$ pairs and particles called gluons which bind the quarks together. In this picture, when two protons pass through each other the point-like quarks usually miss each other—they may however get shaken up with excitation energy. These excited protons then break up into normal ground state hadrons. Occasionally a $q\bar{q}$ or a $q\bar{q}$ collision occurs, and because of their point-like nature a large angle scattering is likely. The scattered quarks themselves do not emerge as free particles, but "dress up" into normal hadrons which frequently have large momentum components transverse to the collision axis. The discovery at the ISR of relatively large numbers of hadrons with large transverse momenta supports this concept of point-like hadron constituents, just as the observation of large angle α particle atom scattering led Rutherford to discover the atomic nucleus.

However much more data are needed on this rather rare type of collision to establish the precise nature of quark-quark scattering, and the next generation of experiments probably requires a large new particle detection system, which would allow the identification and momentum measurement of most of the particles created in the collisions. The importance of the ISR in this field is that these processes have a very strong energy dependence and are therefore less amenable to study in lower energy machines.

Many of the present experiments at the ISR concentrate on lepton production. Four leptons are known (e^- , μ^- , ν_e , ν_μ and their antiparticles). It may be more than a coincidence that we know of four quarks. The leptons do not interact strongly and should only be produced indirectly in hadron-hadron collisions, for example through the production and decay of

One of the intersection regions of the ISR showing the point (centre) at which the two regions cross.

other particles (such as charmed hadrons, see *News and Views*, **262**, 537; 1976) or through $q\bar{q}$ annihilation:

$$q\bar{q} \rightarrow \gamma \rightarrow \mu^+ \mu^-$$

where γ is a virtual photon or a heavy photon-like particle, for instance the J/ψ . (Samuel Ting and Burton Richter were awarded the 1976 Nobel prize for physics for the discovery of this particle, see *Nature*, **263**, 714; 1976.) Current experiments are searching for new J/ψ -like particles and, if the annihilation mechanism is correct, are able to map out the q and \bar{q} distributions inside the proton. Many physicists expect new surprises in this field; if so the research programme is completely open ended.

The high energy (and wide energy range) of the ISR is also vital for the study of some other, perhaps less fashionable, processes. I mentioned earlier the possibility of one proton becoming excited into a higher energy state in a collision; the other proton may recoil in its ground state acting only as a "spectator". The energy or mass of these excited states grows linearly with the effective collision energy, and reaches values of order 12 GeV at the ISR (compared with about 3–4 GeV at the SPS and Fermilab). Little is known about these massive states, for example their composition in terms of particle type. A related process is expected to "turn on" in the ISR energy range, in which both incident protons emerge un-

changed from the collision except for a small loss of energy. The energy lost by the protons reappears in the form of hadrons which essentially "pop out" of the vacuum (the vacuum is supposed to be full of virtual particle pairs which can materialise if sufficient energy is supplied). If this process does not exist several theoretical ideas must be incorrect; if it does exist it is rather fundamental and should be studied in depth.

The ISR Workshop also discussed possible improvements to the machine itself: higher collision rates, other particles in the beams (antiprotons, deuterons and heavier ions) and higher energy beams. Beams of 120 GeV would be possible if the present magnets were replaced with 5 Tesla superconducting magnets, giving an energy equivalent to that of a 30,000 GeV accelerator. This is clearly a possibility for longer term development, and in my view a most exciting one. Theories which unify the electromagnetic and weak forces predict three very fundamental particles (W^\pm , Z^0) which are responsible for the weak interaction (radioactivity) with masses near 65 and 80 GeV. They would probably be produced at the ISR if it were upgraded in this way, and much of the other physics studied at present would greatly benefit from an extension in energy.

I believe most of the participants left the Workshop with considerable enthusiasm for the future possibilities of the ISR. First, there are many questions about very high energy inter-

actions that need answering, and which appear to be answerable with the machine as it is today, but are beyond the range of lower energy machines. Second, improvements to the machine and the detectors will widen the scope of these investigations, and it is not unreasonable to suppose that new surprising discoveries will be made. Finally the investment made in the ISR has given Europe a unique facility which could be made a stepping-stone into a completely new energy region. \square

Pair-breaking in superfluid ^3He

from P. V. E. McClintock

STUDIES of the way in which negative ions move through liquid ^3He have resulted in a particularly revealing demonstration of the superfluid properties which it exhibits in the temperature range around 1 mK. The experiments, carried out at Helsinki Technical University by A. I. Ahonen, J. Kokko, O. V. Lounasmaa, M. A. Paalanen, R. C. Richardson, W. Schoepe and Y. Takano, and reported in *Physical Review Letters* (37, 511; 1976), represent the first successful investigation of ion motion in the recently discovered superfluid phases of the liquid.

The so-called ion formed when an excess electron is injected into liquid helium is actually a semi-macroscopic spherical structure with a diameter of around 3 nm and an effective mass about a hundred times greater than that of a helium atom. Being negatively charged, ions may be directed by means of externally applied electric fields and their arrival at a collecting electrode may be detected as a current. They therefore constitute particularly convenient probes for elucidating the behaviour of the liquid, and they have already been employed to excellent effect in gaining insights into the nature and fundamental properties of superfluid ^4He . Comparable investigations of superfluid ^3He are, of course, considerably more difficult because of the exceedingly low temperatures which must be achieved and maintained: the superfluid transition temperature of ^3He is near 2 mK, or about a thousand times colder than that of ^4He .

The ^3He in the Helsinki experiment was refrigerated, using a nuclear demagnetisation cryostat, to temperatures less than half that of the superfluid transition. The measurements themselves, based on a technique recently developed at Lancaster University, were in essence exceedingly simple. Bunches of ions, injected into the liquid from a field emission tip,

were gated into a drift space of known length which they traversed under the influence of a fairly uniform electric field, finally arriving at a collecting electrode where they were detected as pulses of current. By measuring the time taken to cross the drift space, the characteristic velocity of the ions could thus be determined for a number of different temperatures and electric fields.

Some typical experimental results for the B phase (the form of superfluid ^3He which is stable at low pressure) are shown in Fig. 1. It is strikingly evident that, for any given electric field, the ions travel much faster as the liquid is cooled below the temperature T_c of the superfluid transition. By analogy with the behaviour of ions in liquid ^4He , it is natural to try and account for the general shape of these curves on the assumption that there are two separate types of mechanism by which the kinetic energy of a moving ion may be dissipated: (1) at all finite temperatures the ion travels through the residual gas of normal, that is, unpaired, ^3He atoms which tend to impede its progress; (2) if the velocity of the ion is high enough, additional dissipative mechanisms can come into play whereby the ion creates excitations in the liquid. On this model, the ionic drift velocity which is measured in practice represents an average over the numerous individual scattering and possible excitation creation events which occur during the transit.

For sufficiently small ionic drift velocities, where only (1) need be considered, the velocity-field characteristic is expected to be linear with its gradient defining the ionic mobility. It may be noted from the figure that this is indeed the case and that, as the temperature is reduced, the mobility increases rapidly, consistent with the expected decrease in scattering as more and more of the ^3He atoms fall into the paired states that comprise the superfluid. Indeed, at the lowest temperatures, the mobility apparently became so large that it was impossible to observe the linear region at all. Comparing these results quantitatively with theoretical predictions by T. Soda (in *Proc. 14th Int. Conf. on Low Temp. Phys.*, edit by Krusius, M. and Vuorio, M., 1, 13, North-Holland, Amsterdam, 1975) and R. M. Bowley (*J. Phys.*, C9, L151; 1976), Ahonen *et al.* point out that both of these calculations substantially underestimate the magnitude of the superfluid mobilities. Probably, however, we will not have to wait very long for the theorists to improve their calculations, now that they have the stimulus of some real experimental data.

Fig. 1 The drift velocity v of negative ions moving through superfluid ^3He under the influence of an electric field E , for various temperatures. The behaviour in normal (non-superfluid) ^3He is shown by the full line, and the predicted value of Landau critical velocity for pair-breaking is indicated by an arrow.

Assuming that the observed bending over of the characteristics for velocities above a few cm s^{-1} is the result of mechanisms of type (2), it is natural to enquire into the nature of the excitations which are being created, and there are several possible candidates. For each of these there will be a so-called Landau critical velocity v_L , which the ion must exceed if the general requirement for simultaneous conservation of energy and momentum is to be satisfied during the creation process. At very low temperatures, where dissipation through (1) may be ignored, one would expect that an ion moving under the influence of a small electric field will accelerate without hindrance until it reaches v_L , and that it will then continue moving at a constant drift velocity equal to v_L while dissipating, in the form of excitations, the energy gained from the electric field. Thus, the position where the lowest temperature curve in the figure, that for $T=0.45 T_c$, cuts the velocity axis gives a value of v_L which can be used to try and deduce the nature of the excitations. The simplest assumption, by analogy with the superfluid electron gas in a superconductor which in many respects is a similar system, is that the excitations emitted by the ion are just unpaired ^3He atoms. The Landau critical velocity for breaking apart the pairs of ^3He atoms forming the superfluid may be estimated as about $v_L=6.7 \text{ cm s}^{-1}$, and is indicated by an arrow in the figure. The fact that the curve looks as though it would extrapolate back to cut the velocity axis very close to this point is thus of considerable interest and significance, implying that energy dissipation under these conditions is indeed through the anticipated pair-breaking mechanism, rather than through crea-

tion of the (vortex-like?) excitations which may have given rise to the much lower critical velocities observed in the flow experiment recently performed by R. M. Mueller, E. B. Flint and E. D. Adams (*Phys. Rev. Lett.*, **36**, 1460; 1976) at the University of Florida.

Although a number of important conclusions may be drawn from the present data, the Helsinki experiment—as the authors themselves point out—is really only a beginning. Their principal achievement is to have demonstrated the technical feasibility of using ions to probe the superfluid phases of ^3He . It is to be hoped that future experiments of this type, taken in conjunction with improvements in the theoretical situation, will enable the temperature dependence of the energy gap separating the paired atoms of the superfluid from the (unpaired) excited states of the liquid to be mapped out in detail; it should be possible, using a more carefully designed geometry, to explore the anisotropy of the A phase; and the use of positive ions, to judge from earlier experience in superfluid ^4He , may perhaps enable completely new types of excitation to be created and identified. □

Nitrogen aggregates in diamond

from John Walker

As regular readers of News and Views may remember, nitrogen is a common impurity in diamond, though how exactly it got there and the precise forms it adopts within the crystal are only poorly understood. But a recent paper by G. Davies (*J. Phys. C: Solid St. Phys.*, **9**, L537–L542; 1976) partly resolves the latter question. The question is important, and not only for scientific reasons since it bears on the synthesis of diamond.

Synthetic diamonds are usually yellow, because they contain a small amount (perhaps one part per million) of dispersed nitrogen. That is, each nitrogen atom is isolated from the other nitrogen atoms, and replaces one carbon atom in the diamond lattice. In the current classification these are type Ib diamonds. Natural diamonds of this type are rare—one in a thousand.

The majority of natural diamonds, and all the large, well-formed ones suitable for adorning sceptres and film stars' fingers, are what we call type Ia stones. They also contain nitrogen impurity, in quite large proportions (up to almost one per cent); but in contrast to type Ib the nitrogen is aggregated. It appears that in growing her diamonds

Nature did not use the same process as General Electric and De Beers (fortunately for the gem industry, since yellow diamonds, though quite pretty, lack the sparkle and fire of water-white stones).

So what is the form of these aggregates? Until a couple of years ago we thought we knew the answer. The nitrogen gathered in large clusters, many thousands of angstroms in diameter, along {100} planes—the "platelets" that Evans and Phaal (*Proc. R. Soc. Lond.*, **270**, 538–552; 1962) had discovered by electron microscopy. Unfortunately we were wrong. We do not know what the platelets are, but thanks to earlier work by Davies (*Nature*, **228**, 758; 1970) and by E. V. Sobolev *et al.* (*Sov. Phys. Dokl.*, **12**, 665–668; 1967) we know that they contain little if any nitrogen.

We do know that there are at least two different types of aggregate, the so-called A and B forms, which give rise to characteristic infrared and ultraviolet absorption. What Davies has done in his most recent paper is to study one of the A bands, in fact a sharp line, under uniaxial stress. That is, he has squeezed a rectangular diamond block between two anvils, at stresses of the order of 20,000 atmospheres. As Wedlake has remarked, for diamond this is only a romantic squeeze; but it can nonetheless produce interesting results. Although the diamond lattice is cubic, under stress its symmetry is reduced (to tetragonal, trigonal or rhombic depending on the direction of stress), causing absorption bands to split into two or more components (just like the Zeeman effect in atomic spectroscopy—the splitting of spectral lines by a magnetic field).

Davies has deduced from the splitting pattern that the defect responsible for the A form of nitrogen has trigonal symmetry. The simplest atomic arrangement consistent with this is a pair of nitrogen atoms next to each other ("nearest neighbours"), replacing a pair of carbon atoms in the diamond lattice. Such a model fits in with the other constraints placed by current experimental knowledge: it is not paramagnetic, it is too small to be detected by electron microscopy, and it accounts for the slight increase in lattice parameter observed in nitrogen-bearing diamonds compared with pure specimens.

In a further paper (*Proc. R. Soc. Lond.*, **A351**, 245–265; 1976) Davies and his colleagues, again using uniaxial stress, demonstrate that the well-known H3 absorption and luminescence system in irradiated and annealed diamond has rhombic I symmetry. Davies (*J. Phys. C: Solid St. Phys.*, **5**, 2534–2542; 1972) has already shown that the H3 defect is produced when the A form of nitrogen traps a vacancy or interstitial

carbon atom produced during irradiation. Rhombic symmetry follows neatly from the trigonal symmetry of the A aggregate.

What we do not yet know is did the nitrogen aggregate into pairs by diffusion, or was it created like that during synthesis? What is the atomic arrangement of the B aggregate, and is nitrogen involved in the formation of the platelets? We still have many questions left to answer. □

Electron transfer systems in microorganisms

from D. O. Hall

An International Symposium on Electron Transfer Systems in Microorganisms was held at the CNRS Laboratory of Chemical Bacteriology, Marseilles on November 2–5, 1976.

THE Marseilles laboratory has been active in the biochemistry of electron transfer in anaerobic bacteria for many years and the meeting was held to discuss the requirements of electron transfer at both the cellular and the molecular level.

The genetics of yeast metabolism has been a fruitful subject for research for some time. P. Slonimski (Laboratory of Molecular Genetics, Paris) discussed some of the recently discovered mitochondrial mutants (MIT⁻) which result in deficiencies in various aspects of mitochondrial metabolism. More than a thousand mutants are now available, opening up the possibility that mitochondrial functions for many different electron transfer reagents and enzymes will be available to biochemists to study the details of electron transport and ATP formation.

B. Haddock (University of Dundee) described his work on electron transfer systems in *E. coli* and *Paracoccus denitrificans*. It is becoming clear that

Correction

In the article "Eukaryotic mRNA: trouble at the 5'-end" (*Nature*, **263**, 188; 1976) the formula on page 190 was printed incorrectly. The correct formula is given below.

bacteria possess an electron transport chain containing many of the components familiar from mitochondria, such as flavoproteins, iron-sulphur proteins, ubiquinones and cytochromes. Since these bacteria are simpler to work with we now have, for example, a means of studying proton translocation to verify aspects of the Mitchell chemiosmotic theory and also to look at the role of compounds such as cyclic AMP in determining alternative pathways of electron transfer. Both these organisms can be grown in anaerobic and aerobic conditions, with precisely specified nutritional conditions, sulphate or iron limitation for example, which will affect components of the electron transport chain.

The occurrence of the enzyme superoxide dismutase to protect organisms against the harmful effect of the superoxide which is produced when oxygen interacts with free radicals is now a very active field. Only recently have anaerobic organisms been shown to contain superoxide dismutase. C. Hachikian (CNRS, Marseilles) reported on the isolation and purification of superoxide dismutase from the sulphate-reducing organism *Desulphovibrio*, an obligate anaerobe. This enzyme has iron in its active centre and is similar to the superoxide dismutase from aerobic prokaryotes, such as *E. coli* and the blue-green alga *Spirulina*. One of the hypotheses put forward as to why anaerobes need such an enzyme is that so-called anaerobic organisms need to be tolerant to small quantities of oxygen. The superoxide dismutase may be inherent to these organisms, or may have been acquired from an aerobic organism by plasmid transfer.

I. Probst (Göttingen) reported on the interesting symbiotic relationship between the sulphate-reducing, anaerobic bacterium *Desulphuromonas* and a green, sulphur photosynthetic bacterium *Chlorobium*. *Desulphuromonas* can utilise acetate as its electron donor and sulphur as its electron acceptor; the net energy difference in this reaction is rather small, but is quite sufficient for the organism to grow in symbiotic association with green photosynthetic bacteria. The green photosynthetic organism *Chlorobium* uses CO_2 , in a classic photosynthetic mechanism, with H_2S as its electron donor, and produces sulphur, which is then used by *Desulphuromonas* with acetate as its carbon source to produce CO_2 and H_2S thus completing the cycle.

The recent discovery of three different ferredoxins was reported by A. Xavier and J. Moura (Lisbon Institute of Science and Technology) from *Desulphovibrio gigas*. These ferredoxins exist as trimers or tetramers and interestingly enough are able to catalyse electron transfer at negative

and positive redox potentials in states of oxidation similar to those of the so-called "C-states" of Carter. What Xavier and Moura have shown is that naturally occurring 4Fe-4S proteins are able to exist as oligomers which themselves can give variations in redox potential. If it is a natural phenomenon and not simply induced by association of monomers *in vitro*, this may be the way in which iron-sulphur proteins can alter their redox potential either within a specific monomer or within the molecule as a whole by association of oligomers; oligomers, of course, can be induced by alterations in salt concentration, pH, and so on. This may in fact be one of the ways in which complex iron-sulphur proteins like nitrogenase and hydrogenase may be able to accumulate a number of pairs of charges before they catalyse reactions such as nitrogen fixation and hydrogen evolution. □

Control of external radiation dose

from a Correspondent

An international meeting sponsored by the Society for Radiological Protection and the UKAEA was held on October 19, 1976, at AERE Harwell.

THE protection of the environment has been widely discussed over the past few months. The objective of this meeting was to consider the main sources of occupational exposure which come from external β , γ and neutron radiations. J. A. Dennis (NRPB, Harwell) discussed the concept of dose-equivalent index and related topics. He expressed the personal opinion that the present lack of guidance from the International Commission on Radiation Units on the use of surveying parameters could give rise to overexposures. It is necessary to measure the dose equivalent at different depths in the body and the NRPB has proposed depths of 5 to 10 mg cm^{-2} and 700 mg cm^{-2} for skin and body respectively. J. R. Harvey (CEGB, Berkeley) was keen to introduce the concept of dose equivalent ceiling to avoid any possibility of overexposure. Thus it would be possible that a survey would give a potential dose of 200 mrem in a particular situation whereas measurements with personal dosimeters would give 100 mrem, both being equally valid, and it is on the latter dose that ultimate control would be exercised.

F. W. Spiers (University of Leeds) described the work by himself and T. Ashton to measure the dose to different organs in a man phantom, exposed to isotropic γ -ray sources (energy range 0.05 to 2 MeV). During discussion Spiers suggested that the dose to the active bone marrow was a reasonable approximation to the whole body dose and is approximately the dose under 53 mm of tissue. He also stated that the response obtained by rotating a phantom in a beam produces different results from those obtained by the use of isotropic radiation.

The large differences in shielding required by nuclear reactors and high energy accelerators was brought out by two papers by A. F. Avery (AEA, Winfrith) and G. R. Stevenson (CERN II, Switzerland). The accelerator shielding consists of earth and masses of iron (100 m long by 2 m in diameter) to bring the dose rate down to 1 mrem h^{-1} for occupational locations and 85 $\mu\text{rem h}^{-1}$ at the site fence. Nuclear reactor shielding is required to reduce the dose rate to 0.1 mrem h^{-1} in these areas, but of course far less material is needed.

In contrast to these two papers E. J. Henshaw (Radiological Protection Centre, Liverpool) said radiation levels up to 1 rem h^{-1} were common in fluoroscopy, but these levels are only present for brief periods. Henshaw suggested that it was important to measure the X-ray generator parameters, in particular the potential across the tube. During the discussion it was suggested that it would be of interest to do a comparative cost-benefit analysis between reactor shielding and dose control in radiology departments.

H. W. Julius (TNO, Netherlands) contrasted the film dosimeter and the thermoluminescent dosimeter (TLD) for personal dose control. The former provides much more detailed information but the TLD has advantages of low atomic number, and linearity of response with fewer environmental effects. J. A. Douglas (AERE, Harwell) described some of the work of Cavallini from Italy and his own studies on the limitations of the albedo technique for personal neutron dosimetry. His work had showed that the ratio of the incident to reflected flux of neutrons could not be used to give the energy of the neutrons except in certain circumstances which could apply for a limited range of radiation shields. J. R. A. Lakey (Royal Naval College, London) brought the meeting to a close by discussing what we do when we cannot reduce the dose rate below 2.5 mrem h^{-1} . He emphasised the importance of working schedules and the sharing of the dose between workers. □

Slip-line field theory and large-scale continental tectonics

Paul Tapponnier

Laboratoire de Géologie Structurale, U. S. T. L., Montpellier, France

Peter Molnar

Department of Earth and Planetary Sciences, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

A simple analogy is made between the tectonics of Asia and deformation in a rigidly indented rigid-plastic solid. India is analogous to the indenter and the great strike-slip faults correspond to slip lines. For various indentation geometries, the sense and linearity (or curvature) of strike-slip faults, convergence at the Burma arc and the existence of the Himalayan Burman Syntax, the conjugate strike-slip faults in Mongolia and the extension at the Baikal and Shansi graben can be predicted. Given the horizontal force necessary to support Tibet, an average shear stress of a few to several hundred bars along faults in Asia is predicted, corresponding to the yield stress of rigid-plastic material.

THE pattern of faulting in Asia, as revealed by analyses of Landsat photos and of seismic data (Fig. 1), bears a strong resemblance to the slip-line field calculated^{1,2} and observed³ for plane indentation of a plastic medium by a rigid die⁴⁻⁶ (Fig. 2). The analogous pattern of deformation for these two seemingly unrelated situations suggests that the continuum approach and the physical understanding of indentation of plastic materials, developed by mechanical engineers, could be used to gain further insight into the process by which continents deform when they collide with one another.

Rigid-plastic materials and plane strain slip-line fields

A plastic material is often assumed to be homogeneous, isotropic and perfectly plastic. There is no volume change and no strain hardening. A large class of problems, and those of interest here, assume a state of plane strain for which the two common criteria for the onset of plastic flow, or yielding (Tresca's and Von Mises's), are equivalent. Yielding occurs when the maximum shear stress, $\tau = (\sigma_1 - \sigma_3)/2$, reaches a limiting value, the yield stress, τ_y , where σ_1 and σ_3 are the maximum and minimum compressive stresses, respectively. Because of the mathematical difficulties in matching boundary conditions across the boundary between regions of elastic and plastic deformation and because the deformation in the plastic region is much greater than that in the elastic region, the elastic region is often treated as a rigid solid. Hence the material is said to be rigid-plastic: plastic where the yield stress is reached and rigid elsewhere. Figure 3a shows the stress-strain curve for such a solid.

All analyses are made at the yield point, so that $\tau \leq \tau_y$ throughout the region which deforms plastically. In this plastic

region the slip lines correspond to the maximum shear stress trajectories along which $\tau = \tau_y$. The mean (hydrostatic) stress, $\sigma_h = (\sigma_1 + \sigma_3)/2$, changes along the slip lines when they are curved, in a simple manner that can be determined from the equilibrium (Hencky) equations. Thus, from these equations, the geometry of the slip lines and the stress boundary conditions, the complete stress field in the plastic medium can be obtained easily.

Pure shear occurs on and parallel to the slip lines. They mark lines across which the tangential component of displacement can be discontinuous, as at faults in the Earth. The two types, α and β lines, differ only in sense, and in geologic terminology are right- and left-lateral respectively. As slip lines are lines of maximum shear stress, they must intersect each other at right angles and all traction-free boundaries at angles of 45° .

Solutions to rigid-plastic problems can be divided into those of steady and of unsteady flow¹. For steady flow, the boundaries do not change shape or relative position, and the pattern of flow is independent of time. The drawing of wire is an example. For most tectonic problems, however, it appears that solutions only for unsteady flow are of interest. Again two types of solution can occur. In some cases, the deformation occurs in such a way that, although the region of deformation increases with time and, hence, the boundary conditions change continuously, the geometry of deformation changes only in scale. An example is the indentation of a rigid-plastic medium by an infinite rigid wedge (Fig. 2b). The pattern of deformation changes only by increasing in extent with time, proportionally to the rate of indentation. For most problems, however, the actual shape of the boundaries, and, hence, the boundary conditions, change as deformation progresses. The plane indentation solution shown in Fig. 2a is an example; the slip lines are appropriate only for the onset of yielding.

In principle, it is possible to determine the finite deformation of a rigid-plastic medium by successively and incrementally calculating the deformation for the given boundary conditions and re-evaluating the boundary conditions on the deformed boundaries. For the analogy with Asian tectonics, however, we do not know with confidence the detailed history of deformation, and therefore sophisticated computation of complicated deformation histories probably will not be very useful at present. On the other hand, we think we do know, qualitatively, how deformation occurred during the past few million years, and we are more concerned with understanding it than speculating on the previous history of deformation. Fortunately, because the solutions for plasticity problems are incremental, in so far as strain hardening can be neglected, knowledge of the previous history of deformation is not necessary for calculation of the slip lines at a given stage of the deformation.

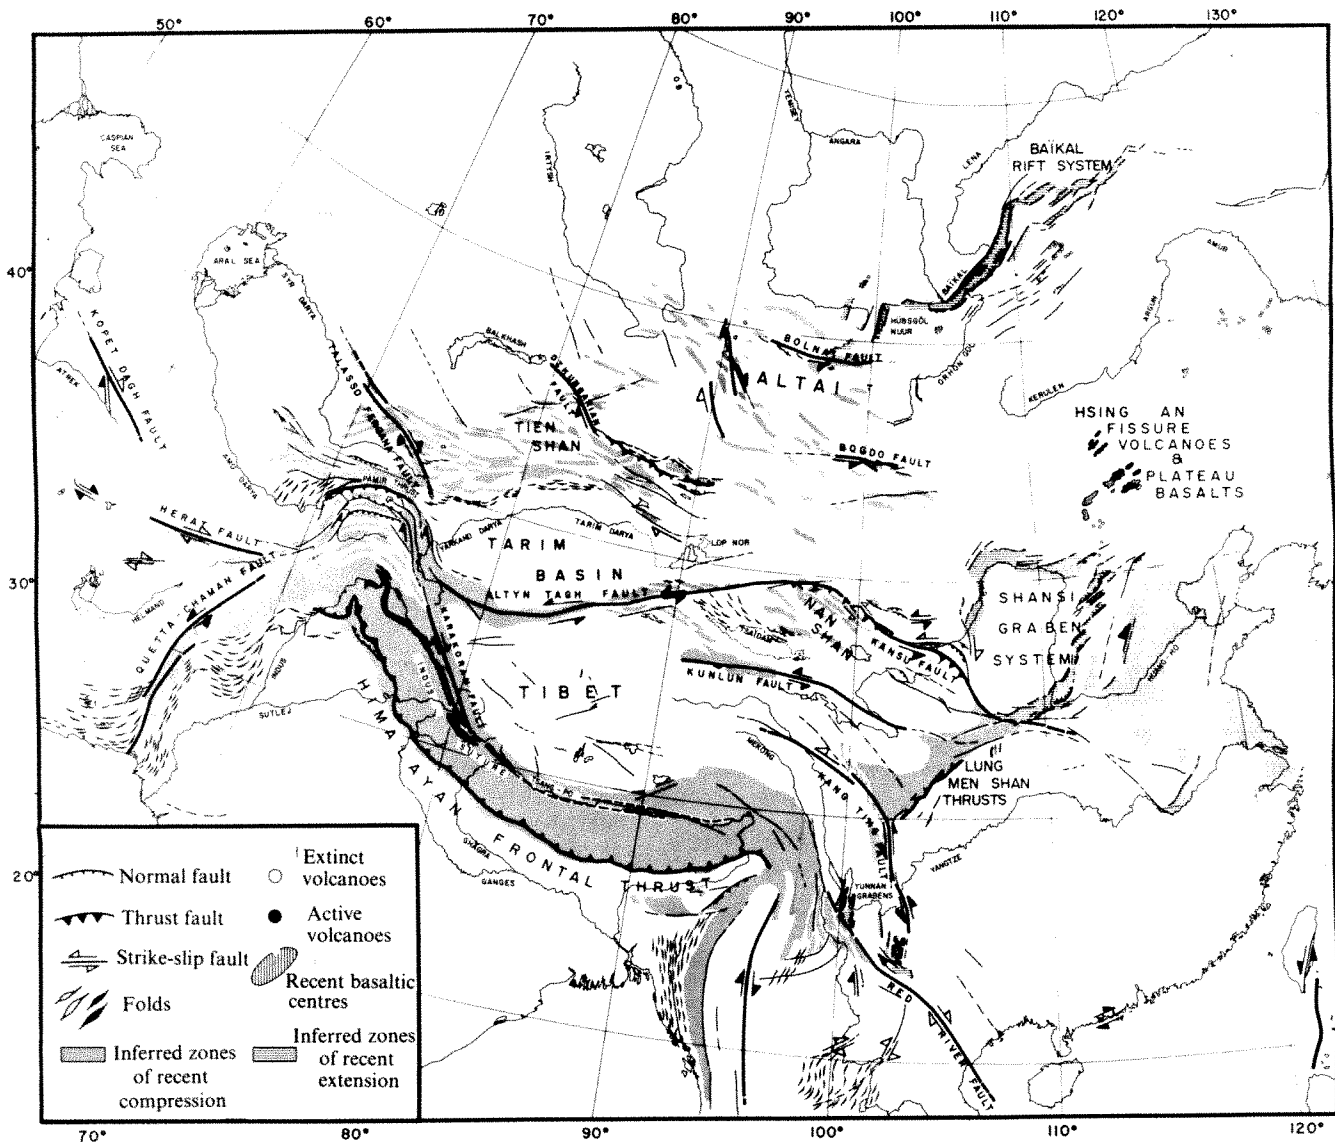

Fig. 1 Simplified map of recent tectonics in Asia⁵. (—) Major faults; (—) sense of motion; (▨) region of crustal thickening; (▨) regions of crustal thinning.

Assumption of plasticity and plane strain in Asian tectonics

Although in detail there are obvious violations of the basic assumptions made for the solutions for slip lines of rigidly indented rigid-plastic media when this formalism is applied to Asia, the similarity of the patterns alone is enough to pursue the analogy further. Although strain may accumulate elastically during intervals between earthquakes, the total strain in Asia since the collision of India is a few tens of per cent⁶. Elastic strain at any instant and the total change of volume in the region will be negligible portions of the total deformation.

If the stress on and near active faults alternately accumulates and then drops during earthquakes, the regional stress-strain curve may resemble that shown in Fig. 3b. Although the stress may vary with time, when averaged over a long time (many earthquakes), the regional stress-strain curve would be similar to that shown in Fig. 3a, for a perfectly rigid-plastic solid. In the Earth, at slow strain rates, strain hardening may be a minor effect, particularly along fault zones where gouge alteration and strain heating are likely to occur. Moreover, at depths ≥ 20 km fault creep is likely to play an increasingly important role in the deformation of the crust. At even greater depths, the temperature is appropriate for plastic deformation to be

dominant in most rocks at grain scale. Thus if most of the lithosphere at depth behaves plastically, in spite of the pressure dependent strength of the rocks in the top part of the crust, the assumptions of rigid plasticity and isovolumetric deformation are likely to be reasonable over a large scale and long time (10^5 yr) for the behaviour of the continental lithosphere as a whole.

Also, a plane horizontal strain analysis is justified for most of the deformation in Asia in the past 40×10^6 yr since the largest displacements (of the order of several hundred km (refs 5, 6)) seem to be horizontal movements along great vertical strike-slip faults.

Plane horizontal strain, however, does not take place everywhere in Asia. Important crustal thickening occurs at the Himalayas and Pamirs, and to a lesser degree in the Tien Shan and Nan Shan (Fig. 1). Further to the north-east (Fig. 1), crustal thinning occurs in the Baikal and Shansi graben belts. The deformation in these narrow mountain and graben belts, in fact, is close to plane vertical strain⁷⁻⁹, but is likely to be a fraction of that due to large scale strike-slip faulting, for two reasons: first, whereas strike-slip faulting is compatible with steady state deformation for long periods of time, in any given area crustal thinning is limited by the thickness of the crust itself and crustal thickening by the fact that, with increasing elevation

of the mountains, an increasing amount of work must be done against gravity. Second, the horizontal maximum principal stress necessary to cause plane strain ($\sigma_1 = \sigma_3 + 2\tau_Y$) is less for plane horizontal strain through strike-slip faulting where $\sigma_3 < \sigma_2 = \sigma_z$ than that for plane vertical strain through thrusting and crustal thickening where $\sigma_3 = \sigma_z$. Crustal thickening will occur when σ_1 is especially high as is the case in front of the indenter or where there are pre-existing weak fault zones of the right orientation, as might be the case in old orogenic belts such as the Tien Shan or the Nan Shan (Fig. 1). In fact, that the crust and upper mantle structure of Asia is not homogeneous and may not be isotropic even on a scale of a few tens of km may be one of the causes of the differences between the fault pattern in Asia and the slip-line fields.

Indentation geometry and Asian tectonics

The deformation of a rigid-plastic body caused by indentation depends strongly on the shape of the indenter. If the indenter is flat, deformation extends into the semi-infinite rigid-plastic medium to a distance approximately equal to the width of the

Fig. 3 *a*, Deviant stress-strain curve for rigid-plastic and elastic-plastic body. Once the yield stress, τ_Y , is reached, plastic strain proceeds at constant stress (no strain hardening). *b*, Qualitative regional stress-strain behaviour of rocks in top part of crust. Slow accumulation of elastic strain is followed by sudden stress drops during earthquakes. With increasing regional strain, average deviant stress may oscillate about roughly constant value.

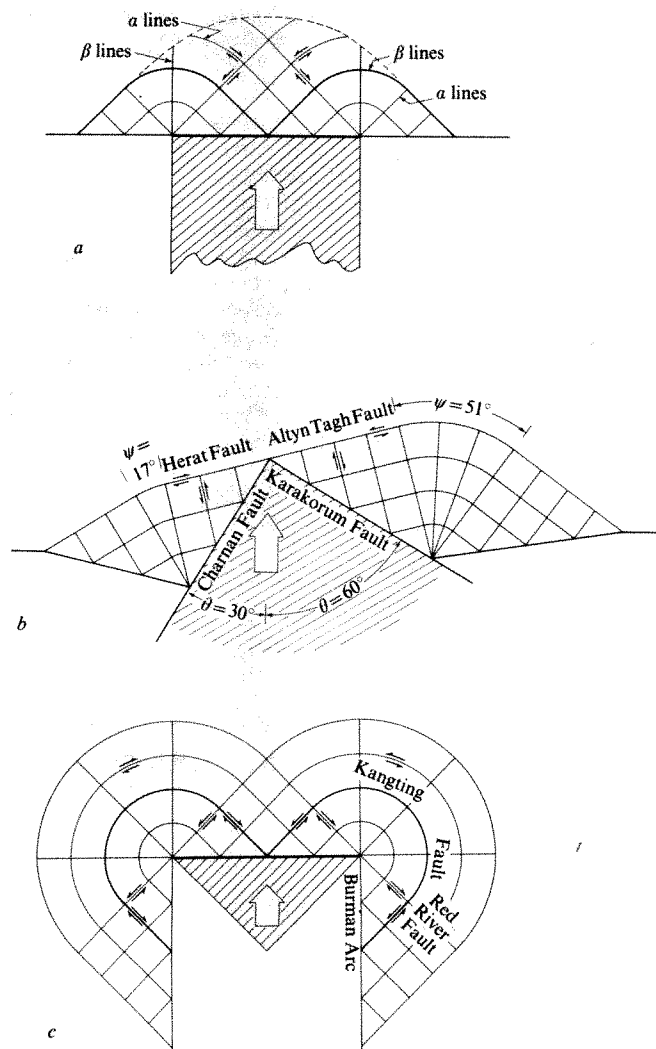

Fig. 2 Plane indentation of semi-infinite rigid-plastic media by different rigid dies. Arrows indicate sense of shear along slip lines. Principal stresses σ_1 and σ_3 bisect small quadrilaterals delineated by slip lines. The names of corresponding major tectonic features are indicated. *a*, Flat rigid die; *b*, rigid wedge—similar to the situation that occurs at the Pamirs (Fig. 1) (western end of the Himalayas); *c*, flat triangular indenter and hollowed-out medium, similar to situation which arises at the Himalaya-Burman syntaxis (Fig. 1) (eastern end of the Himalayas).

indenter (Fig. 2a). If the indenter is a wedge, at any given time the deformation may or may not extend further into the medium than the wedge itself depending upon the angle of the wedge (Fig. 2b).

Assuming the boundary of (rigid) India to be along the Himalayan Front and through the Kirthar and Sulaiman Ranges in Pakistan, parallel to the Chaman Fault, it seems that India has penetrated far into (plastic) Asia (Fig. 1), and therefore the analogy⁵ in Fig. 2a can be improved upon. In the western Himalayas and in Pakistan, the boundary of India is similar to that of a wedge. Note that the Herat and Altn Tagh faults are approximately parallel to the slip lines that would be created by wedge indentation (Fig. 2b). As the direction of motion between India and Eurasia is approximately north-south, the western edge of the Indian wedge is steeper than the eastern edge. Correspondingly, the Altn Tagh fault strikes more north-easterly than the Herat fault. The right lateral North Anatolian fault in Turkey⁴ and the left lateral Great Kabavi fault in Iran¹⁰ have an analogous relationship to Arabia, which appears to act as a wedge into Eurasia further west.

This simple analogy would predict strike-slip motion along the boundaries of the wedge and the rigid-plastic medium (Fig. 2b). Strike-slip motion of the right sense is observed for both the Chaman fault and the Dead Sea fault. There is also evidence for strike-slip faulting along the Zagros suture zone¹¹ and the Karakorum fault^{5,12}. In addition, however, thrust faulting and crustal thickening occur in both the Zagros and the Himalayas^{4,5,13}. The direction of thrust faulting is approximately parallel to the orientation of the maximum compressive stress in the plastic material (Fig. 2b).

An obvious feature of Asian tectonics is that deformation occurs over a vast area north-east of the Himalayas. If the wedge indentation analogy held for all of Asia, we might expect deformation north-east of the Himalayas to be bounded approximately by the Altn Tagh fault, just as deformation does not extend far north-west of the Herat fault. A possible explanation for the widespread deformation north-east of the Himalayas lies in the fact that the trend of the Himalayas to the east curves and becomes approximately perpendicular to the direction of relative motion of the plates. Thus the analogy with the indentation solutions in Fig. 2a would be more applicable to this region.

We think that the pattern of faulting north, east and even south-east of the eastern Himalayas supports the analogy with plane indentation by a flat indenter. The Kunlun and Kangting faults are approximately parallel to β lines. The marked curvature, particularly of the Kangting fault, compared with the straight Altn Tagh and Herat faults would be expected from their proximities to the edge of a flat indenter (Fig. 2a) and to a wedge (Fig. 2b) respectively.

For the region at the eastern end of the Himalayas an even

Fig. 4 Plane indentation of a bounded rigid-plastic medium². *a*, Width of plastic block is ~ 4.4 times width of indenter. Mohr circles on right show stress state at different points of field. σ_h decreases away from indenter as function of angle λ travelled along slip lines and becomes negative near boundary opposite indenter. *b*, Secondary tension may be cause of crustal extension at Baikal rift system.

more appropriate analogy than plane indentation of a flat-sided rigid-plastic medium is with the indentation of an already indented or a hollowed-out medium (Fig. 2c). For this case, the slip lines continue to curve around 180° in order to intersect the 'north-south' boundaries at 45° . In our interpretation of the Landsat photos, the Kangting fault curves around so that east of the Himalayas it trends north-south before becoming lost in the complications of the tectonics further to the south^{5,6}. In addition, the right lateral Red River fault^{5,6} is approximately parallel to an α line. Although this fault is longer than might be expected from the analogy in Fig. 2c, this analogy is strongly supported because it predicts not only the curvature and sense of motion on the Kangting fault but also the sense of motion and trend of the Red River fault.

For us a particularly puzzling feature was the Burman arc, in front of which are a series of folds and east-directed thrusts

and beneath which lies a belt of intermediate-depth earthquakes. Both observations imply a recent eastwards underthrusting beneath the arc. Thus, underthrusting of India beneath the Himalayas in a northerly direction and beneath the Burman arc to the east or south-east occurred simultaneously. In the indentation problem in Fig. 2c, material flows around the edge of the indenter and back in towards it. By analogy, we would expect India to squeeze part of Asia out of the way, so that this part of Asia extrudes around the edge of India and then encroaches upon its eastern side. As the Indian subcontinent is very narrow in eastern India between the Bay of Bengal and the Himalayas, oceanic lithosphere would have underthrust the Burman arc. Therefore resistance to the encroachment of extruded Asia would be less than if it encountered continental lithosphere. The Himalayan-Burman syntaxis and the surrounding tectonics are analogous to a corner in an indenter and the

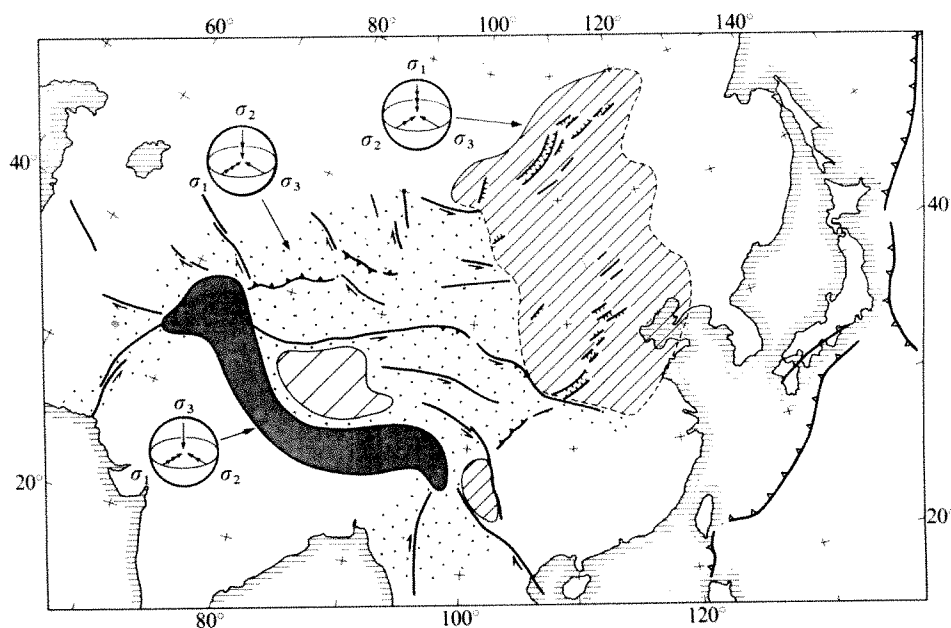

Fig. 5 Distribution of tectonic styles in Asia. Bold lines represent major faults (Fig. 1) (open thrust fault symbol for Pacific subduction zones). Dark shaded area—region of major crustal thickening, dotted area regions—where strike-slip faulting occurs, hatched area—normal faulting and crustal thinning. Corresponding stress states are indicated.

surrounding deformation when the indenter penetrates deeply into a rigid-plastic medium.

Boundary conditions at the limits of the indented block

The pattern of deformation in plane plastic strain also depends upon the shape of the boundaries, of the rigid-plastic medium, as is already clear from the differences in slip-line fields for the situations shown in Fig. 2a and c. For plane indentation as shown in Fig. 2, it is assumed that the rigid-plastic medium extends to very large distances compared with the width of the indenter. When a plastic block of finite width is indented, the slip-line field is of the type shown in Fig. 4a. Plastic yielding occurs in the region between the indenter and the symmetric pair of slip lines that leave the corners of the indenter and intersect each other at the opposite side of the block. Thus the plastic region becomes wider as the ratio of the width of the block (h) to the width of the indenter (a) increases (Fig. 4a). When this ratio reaches ~ 4.4 , the deformation changes drastically to resemble that in Fig. 2a; material flows around the edges of the indenter instead of forcing the two parts of the block to separate rigidly away from a narrow zone of plastic flow between them². Because the lithospheric plates are bounded, the slip-line field in Fig. 4a might be more appropriate for some problems than that in Fig. 2a. In a perfectly plastic material, the slip-line field will presumably be that either in Fig. 2a or in Fig. 4a, but not both, and not a combination of them. In the Earth, it is possible that elements of both situations might find analogues simultaneously, both because the continents are not homogeneous and because the shape of the plate boundaries and the boundary conditions are more complicated than in the idealised situations of Figs 2 and 4.

Perhaps the most interesting characteristic of slip-line fields of the type shown in Fig. 4a is that a tensile state of stress (secondary tension²) develops in the region adjacent to the boundary opposite the indenter. The cause of this tension is the

decrease of σ_h in the plastic medium away from the indenter. This decrease is expressed in Hencky's second theorem¹⁻³

$$\sigma_h = \sigma_{h(i)} - 2\tau_v\lambda$$

where $\sigma_{h(i)}$ is the maximum hydrostatic pressure in front of the indenter and λ the angle rotated clockwise along β lines and anticlockwise along α lines (Fig. 4). Along with σ_h both principal stresses σ_1 and σ_3 decrease proportionately to λ (Fig. 4a). In the extreme case shown in Fig. 4a, where $h/a \simeq 4.4$, σ_h is reduced enough near the apex of the field that all stress components are tensile. σ_3 becomes negative already in the middle of the field. This basic pattern is observed for all slip-line fields of the class shown in Fig. 4.

If the analogy of plane horizontal strain was strictly applicable to the Earth, then at a given depth the lithostatic stress σ_z would be equal to the intermediate stress $\sigma_2 = \sigma_h$. In the Earth, σ_z need not always be equal to σ_h , and when it is not, plane horizontal strain should not occur. There are two extreme situations in which this might occur: when $\sigma_z > \sigma_1 = \sigma_h + \tau_v$ or when $\sigma_z < \sigma_3 = \sigma_h - \tau_v$. These are likely to happen far from the indenter or close to it, respectively. Far from the indenter, the stress state will be appropriate for crustal thinning and the formation of graben (Figs. 4b and 5). We think that the Baikal Rift and Shansi grabens are a consequence of the stress system in Fig. 5, which is analogous to that in the area of secondary tension in Fig. 4. The predominantly normal faulting, the direction of extension and the relative position of the area in which it occurs to the Himalayas are appropriate to the conditions in Fig. 4b.

Deformation near the indenter, and mountain building

Near the indenter, σ_h is maximum and can be very large. When indentation starts it is likely that it will be large enough that σ_z will be the least compressive stress. Consequently, thrust faulting and crustal thickening will take place in the Earth. This in turn will lead to an increase in elevation and therefore to an increase in σ_z at a given depth below sea level. Plane horizontal strain will not take place until σ_z is large enough to be approximately the intermediate principal stress. At this stage, deformation may proceed through strike-slip faulting. This pattern of a first major phase of deformation with shallow thrusts and folds and a late phase of predominantly strike-slip faulting is the basic pattern to be found in most ancient orogenic belts⁸.

When plane horizontal strain is the dominant mode of deformation, then the mean elevation in any given area should reflect the local value of σ_h . The high altitude of Tibet and the general decrease in elevation away from Tibet in Asia may be a manifestation of the decrease in σ_h . Thus we think that both the distribution of tectonic styles in Asia (Fig. 5) and the decrease in mean elevation away from the Indian indenter may reflect a variation of σ_h similar to that predicted by the analogy in Fig. 4a.

The yield stress of Asia

For simple indentation geometries, the pressure σ_1 applied by the indenter and the yield stress are simply related. For the case in Fig. 2a, $\sigma_1 = 2\tau_v(1 + \pi/2)$; for that in Fig. 2, $\sigma_1 = 2\tau_v(1 + \pi)$; and for wedge indentation (Fig. 2b), $\sigma_1 = 2\tau_v(1 + \psi)$, where ψ is related to the wedge half angle θ by (see ref. 1)

$$\cos(2\theta - \psi) = \frac{\cos\psi}{1 + \sin\psi}$$

For $\theta = \pi/4$, $\psi \simeq 0.575$.

Assuming Tibet to be in isostatic equilibrium, we can estimate σ_1 for different depths of compensation. Because Tibet

Fig. 6 Schematic plot of lithostatic pressure versus depth under both Tibet and normal crust. Down to normal Moho (h) the difference in lithostatic pressure is approximately constant and proportional to elevation difference $(1.2-1.4) \times 10^8$ Pa. Pressure difference then decreases to zero at depth of compensation h_c . Average value of pressure difference over thickness of layer above depth of compensation is $\sim \sigma_1$, the stress India applies to Eurasia in the plane indentation analogy.

is 5 km higher than the surrounding stable continental areas, for all depths shallower than the depth of compensation, the lithostatic pressure will be greater than that beneath the surrounding stable areas (Fig. 6). If we integrate this pressure difference from the surface to the depth of compensation, we obtain an estimate of the force per unit length, or the average pressure times depth of compensation, acting along the boundaries of Tibet^{14,15}. The value of this quantity depends upon how compensation occurs, but for all models in which compensation occurs primarily by crustal thickening beneath Tibet, the value is $\sim 5 \times 10^9$ Pa km⁻¹ (1 bar = 10^5 Pa).

By dividing this number by the thickness of the zone, H , assumed to behave analogously to a rigid-plastic material, we obtain an average estimate of σ_1 . For a 100-km thick zone, $\sigma_1 = 5 \times 10^7$ Pa. From the relationships above, the yield stress, τ_y , would be between $\sim 6 \times 10^6$ and 1.6×10^7 Pa. For a 50-km thick zone, these values should be doubled.

These estimates of σ_1 are only approximate and depend upon the assumption that the elevation of Tibet and the compensating mass deficiency are not maintained by vertical shear stress. Moreover, they represent average pressures, averaged over an assumed thickness (H), in which mechanical properties vary markedly with depth. If the yield stress estimated above was controlled essentially by the strength of the faults in the upper crust, where strain is relieved by earthquakes, the estimated strength of this brittle region would be larger than the values of τ_y given above.

For a range of thickness for brittle deformation of 20–40 km (ref. 16), the average stresses on faults would be 2.5–5 times larger than those estimated above, that is as small as 1.5×10^7 Pa or as large as 8×10^7 Pa. The number of assumptions make it impossible to be more precise. Moreover, stress could concentrate in localised regions on faults (asperities) to much higher levels, and the average stress may not reach 1.5×10^7 Pa for all earthquakes. In any case, the estimated range of average shear stresses on faults is higher than nearly all calculated stress drops of earthquakes (10^4 – 10^7 Pa), but is $< 10^8$ Pa.

Summary

When the pattern of faulting in Asia is compared with slip-line fields calculated for various plastic plane strain indentation problems several seemingly unrelated phenomena in Asia appear to have a common cause. India behaves like a rigid die that indents the rest of Eurasia, causing deformation over a large area that resembles deformation in rigid-plastic media. The linear Herat and Altyn Tagh faults are similar to α and β lines, respectively, caused by wedge indentation by north-western India. The more curved Kunlun and Kangting faults

are similar in sense and trend to slip lines near the edge of a more planar indenter, in eastern India. The right lateral Red River fault and the convergence at the Burman arc are parallel to α lines and the direction of plastic flow, respectively, for deformation near the corner of an indenter that has already penetrated deeply into a rigid-plastic solid. The simultaneous convergence at the Himalayas and flow around its eastern end causing convergence at the Burman arc is responsible for the Himalaya–Burman syntaxis. Tension is predicted at a large distance from a flat indenter, and the Baikal Rift Zone and Shansi Graben may be consequences of an analogous state of stress in Asia. From an estimate of the indentation pressure needed to maintain the high elevation of Tibet, we estimate that the average yield stress in a 100-km thick zone in Asia is $\sim 10^7$ Pa. If all of the yielding occurs by stress accumulation on faults and subsequent stress drops during earthquakes to a depth of 20–40 km, the average stress on the faults is a few hundred bars and less than a kbar.

We think that the analogy of plastic plane strain with the tectonic processes in Asia supports the contention that most of the tectonics of Asia are caused by the collision of India with Eurasia and provides a unifying explanation for the phenomena occurring there and in continental collisions in general. This type of approach may lead to an even more general understanding of both the geographical distribution of different tectonic styles within continents at given epochs and the succession in time of different tectonic phases in a given continental area.

C. Goetze, M. Mattauer and F. McClintock clarified several points in this paper, and G. Garcia drafted the figures. This research was supported by the NSF, by the Laboratoire de Geologie Structurale and by an Alfred P. Sloan Fellowship.

A complete skeleton of the Late Triassic ornithischian *Heterodontosaurus tucki*

Albert P. Santa Luca

Peabody Museum, Harvard University, Cambridge, Massachusetts 02138

A. W. Crompton

Museum of Comparative Zoology, Harvard University, Cambridge, Massachusetts 02138

Alan J. Charig

Department of Palaeontology, British Museum (Natural History), London SW7 5BD, UK

The first ornithischian dinosaur to be found in the Triassic (other than very fragmentary material) was Heterodontosaurus tucki from South Africa, described¹ on its skull. The postcranial skeleton of another H. Tucki is described here. Heterodontosaurus is compared with its sympatric contemporary Fabrosaurus, the only other well known Triassic ornithischian, and the interrelationships of early dinosaurs are discussed briefly.

LATE Triassic ornithischian dinosaurs fall into two distinct families: the Heterodontosauridae, including the genera *Heterodontosaurus*², *Lycorhinus*², *Abriotosaurus*² and *Lanasaurus*³, and the Fabrosauridae with the single genus *Fabrosaurus*⁴⁻⁶. (*Fabrosaurus*, however, is considered by some⁷ to be gen. indet.) The general structure of the skull in these two families is known in broad detail^{1,4,5,7-9}, and in *Fabrosaurus* the postcranial skeleton too is fairly well known⁶. Very little has been published hitherto, however, on the postcranial skeleton of *Heterodontosaurus*. This article is essentially a brief account of a virtually complete skeleton of *H. tucki*.

The specimen (South African Museum no. K1332) was discovered in December 1966 in the Upper Red Beds of the Stormberg Series, at a height of about 1,770 m above sea level on the northern slopes of Krommespruit Mountain in the District of Herschel, Republic of South Africa. More complete locality data will be published when the skull and skeleton are described in detail. The scapulo-coracoid, humerus and hand of the specimen have already been partly figured elsewhere¹⁰, though to a very small scale. The only other Triassic ornithischian known with postcranial material worth mentioning is the poorly preserved and fragmented *Pisanosaurus mertii* (ref. 11 and J. F. Bonaparte, unpublished) from the Ischigualasto Formation of Argentina.

Fig. 1 *Heterodontosaurus tucki*. The specimen described in the text (SAM no. K1332).

The skeleton of *Heterodontosaurus* described here is preserved in an articulated condition with little displacement or distortion (Fig. 1). Figure 2 is the first ever complete reconstruction of the skeleton of a Triassic ornithischian. Measurements of some of the elements are given in Table 1.

Axial skeleton

The skull is almost identical with that of the holotype^{1,7,8}. The vertebral column includes 21 presacral vertebrae and 6 sacra, the latter fused together. (These figures, 21+6, compared with the typical thecodontian count of 25+2, suggest that the four additional vertebrae incorporated into the sacrum are all dorsals rather than caudals. The presacral count of 21 has not been broken down into separate cervical and dorsal counts because presacrals 8-10

are transitional in form and the exact position of the boundary between neck and trunk cannot be determined objectively; however, 9 cervicals plus 12 dorsals seems to be the most reasonable allocation.) Twenty-eight caudal vertebrae are preserved in two continuous series, nos 1-11 and (probably) nos 17-33, separated by a gap representing about five vertebrae. It is not possible to estimate accurately the number of vertebrae required to complete the column to the tip of the tail, but it could not have been many because the last vertebrae preserved are very small. Chevrons are present between and below most of the caudals. The remains of ossified tendons lie alongside the neural arches from the middle of the trunk to the posterior end of the sacral series, but they are absent from the tail.

Pectoral girdle and forelimb

The scapula and coracoid are slightly curved, with the concave surface medially; the curve of the coracoid is a little more pronounced than that of the scapula. The dorsal region of the scapula forms a wide blade and appears to have been capped by a cartilaginous extension, while below the blade the scapula narrows to a nearly circular cross section. The wider ventral region supports a well developed acromial process on its anterior margin. A powerful tubercle, presumably for the origin of the scapular head of the triceps muscle, is situated immediately

above the dorsal lip of the glenoid. Near the forelimb lies a roughly rectangular sternal plate with a weakly concave anterior edge, a convex medial edge and straight lateral and posterior edges.

The humerus is slightly twisted along its longitudinal axis; its head is distinct, and the strongly developed deltopectoral crest is so long that it occupies about 40% of the length of the whole bone. There is no olecranon fossa on the posterior surface, in spite of the presence of a distinct olecranon process on the ulna; the anterior surface of the humerus, however, bears a shallow depression above the condyle. The entepicondyle is large, suggesting that the flexor muscles for the forearm and manus were strong. The radius too is slightly twisted about its longitudinal axis, and a small crest, 10 mm high, arises from the middle of the lateral surface of the shaft. The carpus consists of nine

bones: a radiale, an ulnare, a pisiform, a centrale and five distal carpals. The ulnare, with a highly concave proximal surface and a nearly flat distal surface, is the largest of these; a small foramen pierces its dorsal surface. The radiale has the same transverse width as the ulnare but is flatter. Of the distal carpals only V shows reduction, in spite of the fact that digits IV and V are both reduced; indeed, distal carpal V is actually smaller than the pisiform.

The manus is extremely long, the length of digit III being nearly 52% of that of the humerus. The phalangeal formula is 2-3-4-3-2. The distal articular surface of each of the metacarpals I-III is extended dorsally and proximally on to the dorsal surface to an unusual degree; this suggests that the proximal phalanx of the corresponding digit could have been hyperextended on the metacarpal. The distal end of metacarpal I is twisted relative to its proximal end, likewise the distal end of the proximal phalanx of both digits II and III; this would have caused digits I-III to move mediad during flexion, thus producing an effective grasping motion of the manus. Further, the terminal claw-bearing phalanges (unguals) on those three digits bear pronounced flexor tubercles.

Pelvic girdle and hindlimb

The ilium has a long, shallow anterior process which terminates in a small knob-like expansion. The posterior process is slightly shorter and slightly deeper and its posterior

marks the attachment of the ischio-trochanteric and internal tibial flexor muscles¹⁴.

The femur is relatively short and slightly curved with a convex anterior surface; the head projects nearly at right angles to the longitudinal axis of the shaft, the greater trochanter is not separated from the lesser trochanter by a marked cleft, and a pendent fourth trochanter, about 10 mm long, forms an angle of approximately 45° with the axis of the shaft. The tibia is very long, 1.29 times the length of the femur; its proximal articulating surface is not horizontal but slopes downwards and outwards from its medial edge. The proximal part of the tibia is considerably expanded anteriorly into a strong cnemial crest. The head of the fibula also is expanded antero-posteriorly but, even so, its length is only half that of the tibial head; distally the fibula narrows to a thin rod which fuses with the tibia. The astragalus and the calcaneum are indistinguishably fused with the tibia and fibula. The three distal tarsals are fused with the metatarsal heads; thus the lateral distal tarsal caps metatarsal IV, the central caps III, and the medial distal tarsal covers both II and I.

The first four metatarsals are fused to form a single unit, their proportional lengths (taking the sum of their lengths as 100%) being 16.8%, 26.1%, 30.0% and 27.1% respectively. Metatarsal V, however, is reduced to a slender splint. The phalangeal formula is 2-3-4-5-0. Digit III continues the longitudinal axis of its metatarsal, but digit II

Fig. 2 *Heterodontosaurus tucki*. Reconstruction of the complete skeleton.

end also is a little expanded. The pubic peduncle lies almost at right angles to the longitudinal axis of the ilium. A mound-like protuberance and an articular facet on the lateral surface of the ischiadic peduncle increase the depth of the acetabulum. The pubis has a short, deep anterior ramus (15 mm long) and a long, straight, rod-like posterior ramus (pubis proper) which is nearly as long as the ischiadic rod lying immediately above it. Several small rounded tubercles are present on the lateral surface of the anterior ramus; these may be associated with the origins of the ambiens muscle and of the three heads of the pubo-ischio-femoralis internus¹²⁻¹⁴. The ischium is joined to the ilium by a short rounded process, but the process which attaches it to the pubis is flat, wide and expanded. Posterior to this pubic process the ischium narrows to a straight slender rod with a slightly expanded end; there is no obturator process on the ischium, but a prominent and gently curved crest on the central part of the rod probably

diverges medially and IV laterally; digit I is partly reduced and apparently had no role in support during locomotion. The unguals are slightly curved.

Discussion

Heterodontosaurus tucki seems to have been a bipedal cursorial herbivore; this opinion is based mainly on the structure of the manus and pes, the length ratio of tibia to femur, and the structure of the teeth and jaws. Although the forelimb may have been used for locomotion when the animal was moving slowly, for example when foraging, it seems to have been adapted primarily for grasping and tearing. A large olecranon process is usually present in quadrupeds like *Stegosaurus* but absent in bipeds such as *Fabrosaurus*; its presence in *Heterodontosaurus tucki*, however, may have been functionally associated with the powerful arm and highly manipulative hand, for the

Triassic coelurosaur *Syntarsus*¹⁸ also has both an olecranon process and a grasping hand.

The structure of the postcranial skeleton supports the view, based originally upon the skull structure, that the two families of Late Triassic ornithischian dinosaurs (namely the *Fabrosauridae* and the *Heterodontosauridae*) differ from one another in many important features. (This, in turn, accords with the belief that each family had a long independent history dating back to at least mid-Triassic times.) *Fabrosaurus* too was a cursorial biped, sympatric with *Heterodontosaurus*, but it lacks the deep skull of *Heterodontosaurus* and its powerful and specialised masticatory apparatus. Only five sacral vertebrae are present in *Fabrosaurus* instead of six. The deltopectoral crest and whole forelimb are relatively shorter in *Fabrosaurus* than in *Heterodontosaurus*, and *Fabrosaurus* does not have a long and powerful grasping hand. Further, the ulna of

The combination of specialised features seen in *Heterodontosaurus* seems to rule it out as a possible ancestor of known ornithopod ornithischians of later times¹⁸. These features include the nature of the dentition (the closely set teeth worn down to a continuous occlusal surface), the low number of dorsal vertebrae, the large grasping hand, the absence of the obturator process on the ischium, the reduced fibula and the complete fusion of the distal ends of the tibia and fibula with each other and with the proximal tarsals. Although so early in time, *Heterodontosaurus* is far more specialised in these and other characters than are the majority of much later ornithopods—such as *Hypsilophodon* and *Iguanodon* of the Early Cretaceous and even *Thescelosaurus* of the Late Cretaceous. Possible relationships can be discussed in detail only when the available material of Triassic dinosaurs has been more fully prepared and studied.

Bakker and Galton¹⁸ have stated that all Triassic dinosaurs share several common features, such as the shape and direction of the glenoid cavity, the position of the deltopectoral crest, the structure of the hand, the perforation of the acetabulum, the structure of the femur (in particular the position and size of the fourth trochanter), the restriction of femoral movements to the vertical plane, and the mesotarsal type of ankle joint. On the basis of these similarities they have concluded that the three major groups of Triassic dinosaurs (prosauropods, theropods and ornithischians—the last in effect restricted to ornithopods) arose from a central stock of early forms such as *Staurikosaurus*¹⁷, *Ischisaurus*¹⁸ and *Herrerasaurus*^{18,19}. This stock, according to them, could have been derived in turn from a group of thecodontians of which *Lagosuchus*²⁰ is a representative. Such a conclusion, however, seems hardly to accord with the view that even the Triassic ornithischians alone comprise two distinct families with long independent histories, probably going back to no later than mid-Triassic times. A fundamental distinction between the three main groups of Triassic dinosaurs lies in the structure of the pelvic girdle; the form of the prosauropod pelvis does not differ greatly from the primitive thecodontian pattern, whereas the theropod and ornithischian pelves are more highly modified and are also very different from each other. Bonaparte²⁰ is not totally in agreement with Bakker and Galton¹⁸ and still believes (following Charig^{21,22}, Charig *et al.*²³) that both saurischian suborders, as well as the ornithischians, were derived independently from thecodontians. It may well be that some of the common characteristics of Triassic dinosaurs as listed by Bakker and Galton were present in an ancestral thecodontian stock and that others were the result, at least in part, of parallel evolution. Some features of the hand of *Heterodontosaurus* seem to support this view; for example, the facts that metacarpals IV and V of *Heterodontosaurus* are divergent and that digit I does not diverge markedly from digit II are more reminiscent of the hands of thecodontians than of those of early saurischians. Likewise, one of us argues²⁴ that most of the alleged similarities between Saurischia and Ornithischia do not exist or are without phylogenetic significance; the lack of common characters 'primitive' to the supposed taxon Dinosauria, together with the existence of several important differences (not mentioned by Bakker and Galton) between the two orders, suggests that the alleged monophyly of the "Dinosauria" cannot be demonstrated.

It seems undeniable that there was a unity to dinosaur biology which greatly exceeded a few osteological features, but this may well have been due to the fact that all the groups concerned were in any case fairly closely related and had been subjected to the same evolutionary pressures. Whatever view is taken of the controversy concerning the origins and interrelationships of the major groups of dinosaurs, all will agree that it calls for the thorough and detailed preparation and description of the now extensive

Table 1 Selected measurements* of *Heterodontosaurus tucki* (SAM no K1332)

	(mm)
Scapula, maximum length	86.9
Coracoid, maximum length	22.3 estimated
Humerus, maximum length	82.3
Radius, maximum length	58.5 (right)
Ulna, maximum length	67.6
Metacarpals, maximum lengths: I	17.6
II	23.3 (right)
III	22.4
IV	14.5 (right)
Ilium, maximum length	96.9
minimum height above acetabulum	15.0
Pubis, maximum length	125.7 (right)
height of anterior ramus	7.8 (right)
Ischium, maximum length	114.2 (right)
Femur, maximum length	112.2
length of fourth trochanter	9.8
Tibia, maximum length	145.0 (right)
Metatarsals, maximum lengths: I	38.1 (right)
II	59.1 (right)
III	67.9 (right)
IV	61.4 (right)
Combined length of centra of twelve dorsal vertebrae	171.7
Hindlimb (femur + tibia + metatarsal III)	1.89
Trunk (12 dorsal centra)	

* Left side unless stated otherwise

Fabrosaurus lacks the olecranon process and its humerus lacks the prominent entepicondyle. The posterior process of the ilium is shorter and deeper, the pubic peduncle is directed forwards and downwards relative to the long axis of the iliac blade (rather than nearly at right angles thereto as in *Heterodontosaurus*) and there is a large obturator process on the ischium. There are also many differences between the two genera in the structure of the hindlimb. In *Fabrosaurus* the greater trochanter is separated from the lesser trochanter by a deep cleft, the fibula has an expanded distal end and the astragalus and calcaneum are fused neither with the tibia and fibula nor with each other. There is, however, one important feature of the pelvis common to both *Fabrosaurus* and *Heterodontosaurus*—a complete and undescribed pubis of *Fabrosaurus* (SAM no. K1106) shows that the anterior ramus is very similar in shape and even in size to that of *Heterodontosaurus*.

The skeletal remains of *Pisanosaurus*²¹ are very incomplete, but the lower jaw and dentition suggest a closer affinity with *Heterodontosaurus* than with *Fabrosaurus* (Ref. 7 and J. Bonaparte, unpublished). The separate fibula of *Pisanosaurus* with its unreduced distal end and the astragalus and calcaneum fused neither with the tibia and fibula nor with each other might be thought to suggest a relationship to *Fabrosaurus* closer than to *Heterodontosaurus*, but in fact such features are merely primitive and without phylogenetic significance.

collections of Triassic ornithischian dinosaurs and a comparison of these with all available material of their saurischian contemporaries.

We are indebted to Dr T. H. Barry, Director of the South African Museum (Cape Town), for permission to study the specimen described in this article.

Cell length, cell growth and cell division

W. D. Donachie, K. J. Begg & M. Vicente

Department of Molecular Biology, University of Edinburgh, King's Buildings, Mayfield Road, Edinburgh EH9 3JR, UK

When cells of E. coli reach a certain critical length, which is constant in all growth conditions and equal to twice the minimum cell length, they abruptly increase their rate of elongation and divide about 20 min later. Chromosome replication terminates at about this same cell length but is not the signal for the change in rate of cell elongation.

DURING exponential growth, cells of *Escherichia coli* divide after each doubling in their volume. Their growth rate, and thus the frequency at which they divide, depends on the temperature and the availability of nutrients in the culture medium. *E. coli* cells are cylinders with hemispherical ends and, at any one growth rate, the doubling in cell volume between successive division takes place entirely by a doubling in cell length, without detectable change in cell diameter¹. But at each growth rate one observes a different cell volume, length and diameter. The relationship between cell volume and growth rate has been known for some time² and explanations for this relationship have been given^{3–5}. Nevertheless there has not, to our knowledge, been a comparable systematic investigation of the relationship between growth rate and cell length in *E. coli* (although there are several scattered measurements in the literature). We have therefore carried out such an investigation and have found a simple relationship between cell length, cell growth and cell division. This is that individual cells become committed to division and increase their rate of elongation at a fixed length which is independent of growth rate. Moreover, the change in rate of elongation seems to depend solely on the attainment of the critical length and not on other factors such as the termination of chromosome replication (as has been suggested by others^{6–8}). Following a change in growth conditions, cells do not alter their rate of elongation so that it is proportional to their new rate of volume and mass increase, until they attain the critical length. As a consequence, cells change their size and proportions to those characteristic of the new growth rate within one division cycle after the change in growth conditions.

These experimental results are discussed in terms of a modified "unit cell" model⁹ in which the basic unit of cell growth is a section of cell of fixed length, Λ , which extends in length at a fixed number of growth sites (possibly one). The rate of cell elongation therefore doubles after completion of a new unit cell, at length 2Λ . The completion of a new unit cell occurs at the same time as does a signal for the commencement of septation. Septation takes approximately 20 min to complete in all growth conditions.

Relationship between cell length and growth rate

We have calculated mean cell lengths from cell length distributions of *E. coli* B/r (ATCC 12407) growing exponentially at

37 °C in a number of different media (Table 1). A linear regression line was calculated using the method of least squares, which gave

$$\bar{L} = (0.67R + 2.01) \mu\text{m} \quad (1)$$

(where \bar{L} is mean cell length in μm and R is the number of doublings in cell number h^{-1}). The correlation coefficient between the data and the regression line was $r = 0.96$ (Fig. 1).

Average cell lengths were also calculated for a K12 strain, OV2 (Table 1) growing in different media at three different temperatures. These points are also shown in Fig. 1, from which it can be seen that they obey the same relationship as the unrelated B/r. (For these points, $\bar{L} = 0.6R + 2.03$; for which $r = 0.88$.)

The relationship between mean cell length and growth rate shown in Fig. 1 has the following implications: (1) Cell length at a time approximately 20 min before division is approximately the same at all growth rates. (2) This length is approximately twice the minimum length of a cell in any growth condition.

We reach these conclusions as follows. For this argument we rewrite equation (1), without significant error, as

$$\bar{L} = (2 + 2R/3) \mu\text{m} \quad (2)$$

The length of cells at birth (L_B) and at division (L_D) may be calculated, to a first approximation, as proportional to cell age, using the theoretical distribution of cell ages in an exponential population^{1,10}, so that

$$L_B = \bar{L} \ln 2 \quad (3)$$

$$\text{and } L_D = 2L_B \quad (4)$$

(Mathematically more sophisticated methods of estimating these lengths give very similar results when applied to our population; see ref. 12.) Equations (2), (3) and (4) therefore allow us to calculate the lengths of cells at division for all growth rates. But to calculate cell lengths at different stages in the cell cycle, we must make some assumption as to how the cells increase in length (for example, at a constant rate or at a rate which increases as the cell cycle progresses). It is known that cells of *E. coli* increase in length continually over the cell cycle^{1,9,13} but the exact shape of the curve of increase is difficult to determine experimentally, both because of the smallness of the cells and because the change in rate of elongation is only twofold. Nevertheless it can be assumed that this curve lies somewhere between the extreme of a straight line (that is, a constant rate of elongation throughout the cycle) and a linear function in which the rate doubles some time during the cycle.

(An exponential rate of elongation would lie between these two curves.) In the special case in which the rate of increase is linear with the doubling 20 min before division, equations (2), (3) and (4) show that cell length at this time will be the same for all growth rates (Fig. 2b) and that this length is

$$(4 \ln 2) \mu\text{m} = 2.77 \mu\text{m}$$

Even in the cases where length increases exponentially (Fig. 2a) or at a constant rate over the whole cycle, these equations show that cell length 20 min before division will be approximately the same at all growth rates. These lengths will be $2.86 \mu\text{m} \pm 3\%$ and $2.96 \mu\text{m} \pm 6\%$ respectively. Thus cell length must be approximately $2.8 \mu\text{m}$ at a point 20 min before division at all growth rates.

Fig. 1 Mean cell length of exponential phase populations of *E. coli* (data from Table 1) as a function of growth rate (doublings in cell number per hour). The line is the best-fit linear regression calculated by the method of least squares. (Triangles, B/r ATCC 12407; circles, OV2; measurements by light microscopy. Stars, OV2; measurements by electron microscopy).

The minimum length of cells in any steadily growing population may be estimated as the birth length at zero growth rate, using equations (2) and (3). The calculated value for this theoretical minimum length, Λ , is

$$\Lambda = 2 \ln 2 \mu\text{m} = 1.39 \mu\text{m} \quad (5)$$

Thus cell length 20 min before division must always be approximately twice the theoretical minimum cell length. In the special case shown in Fig. 2b, this length must be precisely 2Λ at all growth rates.

In the various models for cell elongation discussed above, it has been assumed that the rate of elongation will be a function of the growth rate in mass and number. This assumption works well for steady growth in a constant environment but it can easily be seen that it cannot apply without modification to cell growth during the transition between one growth rate and another. Thus, taking the model shown in Fig. 2b as an example, if the rate of elongation of a cell were to change immediately to that characteristic of the new environment after a shift from one growth medium to, say, a richer one, cell length at the time of

the next division would be greater than that actually found in the new medium. In fact, if the rate of elongation did change immediately after such a shift, cells would possibly maintain a constant diameter at all growth rates. This is not so. One possible solution to this paradox would be if the rate of cell extension remained the same after a shift to a new mass doubling time and changed to that characteristic of the new growth rate only after the cells reached a length of 2Λ . Our observations support this prediction and, in so doing, also provide evidence that the rate of elongation does change abruptly at about the time and cell length predicted by the model shown in Fig. 2b.

Figure 3a shows such an experiment. At zero time, a selected fraction of small cells was transferred from a poor growth medium (generation time 67 min) to a rich medium (generation time 25 min). The theoretical time of first division after such a transfer is about 60 min (ref. 14) and cells in fact divided between 40 and 60 min (Fig. 3a). The rate of mass increase of the cells increased immediately to the new rate¹⁵ but the rate of elongation remained at the calculated pre-shift rate until it increased abruptly by 5.7-fold after about 45 min. (Figure 3b shows a control experiment in which the selected cells were maintained in the same poor medium as before selection. In this case, the point at which the rate of elongation increased could not be determined, as expected, but the increase in rate over the first division cycle was close to twofold.)

Fig. 2 Calculated course of increase in cell length over cell cycles of various durations, assuming that length doubles over the course of each cycle, that the relationship between mean population cell length and growth rate is given by the straight-line function (equation (2), Fig. 1), and that populations have the theoretical age distribution¹⁶ (see text). The figure shows cell elongation according to two sets of assumptions: a, that the rate of elongation increases continuously according to a logarithmic function, and b, that the rate of elongation is constant but doubles 20 min before division. For clarity, only four growth rates are shown, namely those for generation times of 20 min (· · ·), 30 min (---), 60 min (—) and infinity (— · —). The open circles represent cell length at 20 min before division.

The model we propose to describe cell elongation is therefore that newborn cells elongate at a constant rate which is proportional to the rate of growth in mass. Such newborn cells will always be between Λ and 2Λ in length and will reach 2Λ after a period of growth which is proportional to the initial cell length and the growth rate. In steady growth conditions, the rate of elongation will double at this point. (During a medium shift, this rate increase will be a doubling times the change in growth rate in mass.)

(The possibility that the sucrose gradient selection might perturb the rate of cell elongation may be discounted, since we observe the change in rate of cell elongation at the same cell

Fig. 3 Course of increase of total cell length (●), total cell mass (○) and total cell number (■) in synchronous cultures of *E. coli* B/r ATCC 12407. (Total cell length is calculated as mean cell length \times cell number per cell number at time zero. The error of estimate of mean cell length is $\pm 3\%$). In *a*, small cells were selected by sucrose gradient centrifugation²⁴ from a population growing exponentially in medium 2 (Table 1) with a generation time of 67 min and reinoculated into L-broth + glucose, after which the mass doubling time immediately decreased to 25 min. Cell division took place between about 40 and 60 min. Cell length increased at a constant rate for approximately 40 min and then increased abruptly to a new rate which was about $5.7 \times$ the initial rate. In consequence, the cell length and cell mass changed from those for cells growing at a rate of 0.9 doublings h^{-1} to those for cells growing at 2.4 doublings h^{-1} by the time of the first division in the new medium. The predicted course of cell elongation according to the theory developed in this paper is also shown (— — —). *b*, The result of a control experiment in which small cells from an exponential population with a generation time of 63 min (medium 2) were reinoculated into a fresh batch of the same medium. The selected fraction of cells were slightly larger than those obtained in *a* and there was a small initial stimulation of the rate of mass increase. The theoretical curve for length increase was drawn taking these factors into account. In this case the increase in rate took place at approximately 30 min and was an increase of about $2.3 \times$, as predicted. The insets show the length distributions of the selected populations at zero time, superimposed on the distribution for exponential asynchronous populations in the same growth conditions.

Table 1 Growth rate and cell length

Strain	Medium	<i>T</i>	37 °C <i>R</i>	\bar{L}	<i>T</i>	30 °C <i>R</i>	\bar{L}	<i>T</i>	42 °C <i>R</i>	\bar{L}

OV2	8	30	2.00	3.56	47	1.28	2.89	25	2.40	3.49

OV2 is a spontaneous *ilv⁻his⁻* derivative of *E. coli* K12 M6K (see Table 2). *T* is the cell number doubling time in minutes, *R* is the number of doublings per hour, and \bar{L} is the mean cell length of the population in μm . Media: (1) M9+sodium succinate (0.4%); (2) M9+glycerol (0.8%); (3) M9+glucose (0.4%); (4) M9+glucose (0.4%)+histidine (20 $\mu\text{g ml}^{-1}$)+methionine (20 $\mu\text{g ml}^{-1}$); (5) M9+glucose (0.4%)+casamino acids (0.5%); (6) M9+glucose (0.4%)+casamino acids (0.5%)+tryptophan (20 $\mu\text{g ml}^{-1}$); (7) M9+glucose (0.4%)+casamino acids (0.5%)+tryptophan (20 $\mu\text{g ml}^{-1}$)+cytosine (20 $\mu\text{g ml}^{-1}$)+adenine (20 $\mu\text{g ml}^{-1}$)+uracil (20 $\mu\text{g ml}^{-1}$); (8) Oxoid Nutrient Broth no. 2; (9) Oxoid Nutrient Broth no. 2+glucose (0.4%). All OV2 cultures contained in addition all required auxotrophic supplements (final concentration of thymine was 50 $\mu\text{g ml}^{-1}$). For these measurements, cells were grown in log phase with shaking in liquid medium for several generations and samples taken at a density of 10^8 ml^{-1} (media 1–7) or $3 \times 10^7 \text{ ml}^{-1}$ (media 8 and 9) on to slides coated with a thin layer of agar[®] containing 0.1% sodium azide to prevent further cell growth. Cells were photographed with a Zeiss Ultraphot microscope under phase-contrast optics. Enlarged projections of the negatives were measured⁹. At least 200 cells were measured for each distribution. The error of estimate of \bar{L} was not more than 3%.

length in single cells growing in agar following a shift from a poor to a rich medium.)

Control of rate of cell elongation

We now ask what event in the cell cycle is responsible for the observed increase in rate of elongation which takes place about 20 min before division. It is known that the cell becomes committed to divide (even in the absence of further RNA, protein or DNA synthesis) at approximately 20 min before division¹⁶⁻¹⁸. This transition point in the *E. coli* cell cycle coincides with (1) termination of the oldest round of chromosome replication¹⁹, (2) segregation of the nuclear bodies¹⁴, (3) completion of the period of protein synthesis required for division¹⁶, (4) initiation of termination protein synthesis²⁰, (5) onset of sensitivity to penicillin (activation of autolysins)²¹ and (6) attainment of a particular length. (The first visible signs of septation can be detected within a few minutes of this time²².) One or more of these events might therefore be necessary for the increase in rate of elongation to take place.

It has already been suggested^{6,7} that termination of each round of chromosome replication might be a signal for a doubling in the rate of cell elongation. This suggestion stemmed from observations on the relationship between cell volume, length and radius as functions of the transit time, C , taken by replication forks to travel along the chromosome. According to this model the rate of cell elongation would be determined solely by (1) the number of chromosome termini per cell, and (2) the doubling time for cell mass.

To test this hypothesis, we investigated whether an increase in the rate of cell elongation would take place in the absence of chromosome termination. Step-up experiments, such as that

described, provide a sensitive technique for such a determination. We have therefore shifted cells from a poor to a rich medium in conditions in which chromosome termination was prevented. We found that this does not prevent the increase in rate of cell elongation at the same time as in controls.

For this experiment we used a low thymine-requiring strain, B/r/1 T⁻ (ref. 9) which has the advantage that it is able to increase in mass at the control rate for nearly 1 h after removal of thymine, although DNA synthesis stops immediately. (Thymine auxotrophs of the other strains mentioned here could not maintain this rate for so long. Nevertheless, we have observed that their lengths increase in a similar way to B/r/1 T⁻ during this time.) It should be noted that this strain is about 50% longer than the others described here.

Small cells were selected as before from an exponential population in minimal medium plus thymine (generation time 56 min) and transferred to a rich medium plus or minus thymine. After transfer both aliquots grew initially with a mass doubling time of 33 min (Fig. 4), although growth in the thymine-starved aliquot slowed down by about 50 min after transfer. Synchronous division of the control cells took place between 35 and 45 min while the thymine-starved cells showed only a small increase in number. The initial rate of length increase in both cultures was initially that appropriate to the pre-shift growth rate but changed abruptly to the expected higher rate (roughly 3.8 times greater) at about 30 min in both cultures. We consider that this experiment shows that termination of chromosome replication is not required as signal for the observed abrupt increases in rate of cell elongation.

This conclusion is further corroborated by the observation that an increase in the number of chromosome termini per cell,

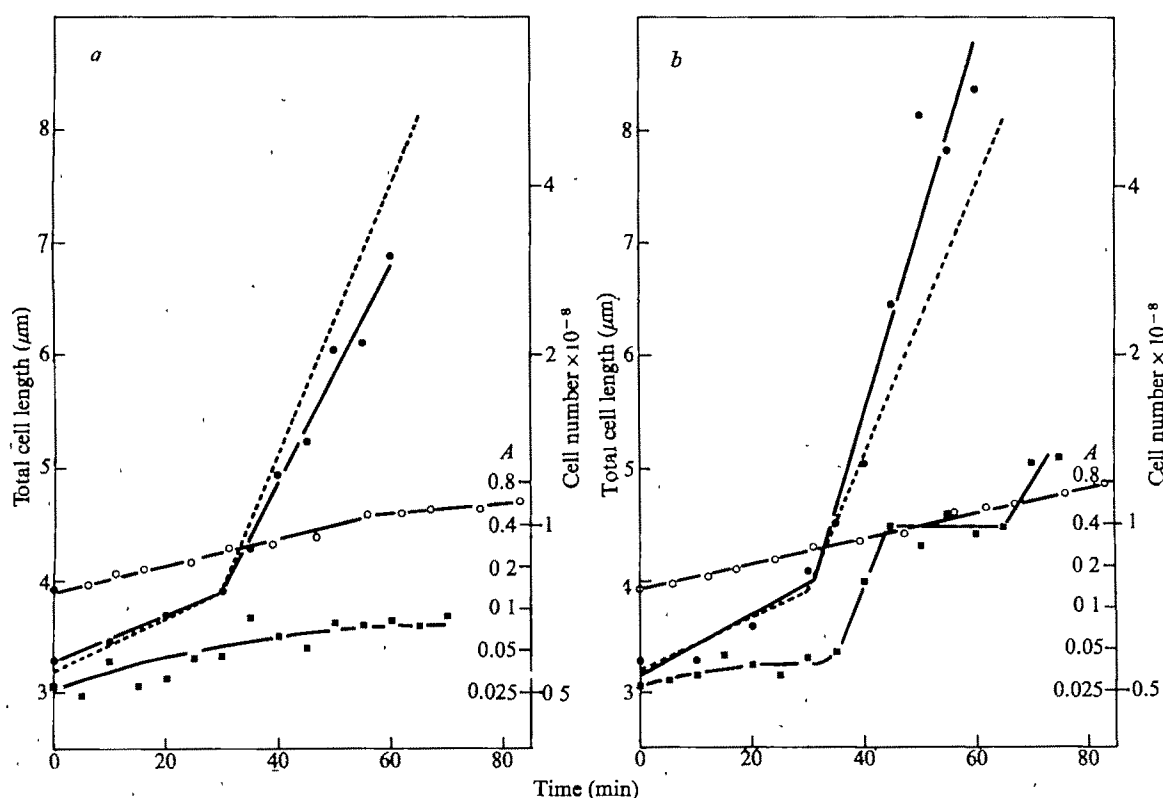

Fig. 4 Increase in total cell length, mass and number (symbols as in Fig. 3) following transfer of selected small cells to a richer medium, *a*, with or *b*, without further chromosome replication. A homogeneous fraction of small cells was selected by sucrose gradient centrifugation of a population of cells of *E. coli* B/r/1 T⁻, growing with a generation time of 56 min in medium 2 + thymine (50 μg ml⁻¹) and reinoculated into medium 7 (Table 1) *b*, with or *a*, without added thymine. In both cases the mass doubling time changed initially to 33 min but growth gradually slowed after about 50 min in the absence of thymine. DNA synthesis in this strain stops immediately after removal of thymine from the medium²³. In the presence of thymine, but not in its absence, synchronous cell division took place between 35 and 45 min and again after 65 min. (A small increase in cell number took place initially in both cultures, due to the separation of a proportion of cell pairs present in the selected fraction.) In both cultures total cell length increased initially at about the same rate and then increased abruptly at about 30 min. (This rate change was slightly higher than predicted in *b* and slightly lower than predicted in *a*, probably due to the general slowing down in growth after prolonged thymine deprivation, but the change in rate is clearly seen in both cases.)

caused by premature termination in the absence of cell growth, also does not affect the rate of cell elongation when growth is resumed. This experiment is described in Table 2.

Model of cell growth and division

We may summarise our observations as follows: (1) Cells divide about 20 min after reaching a particular length, 2Λ , (which is about 2.8 μm for a K12 strain and for one B/r strain), independent of the growth rate of the cells (2) The rate of cell elongation changes at about this same length. If growth conditions remain constant, the rate doubles at this point, whereas if growth conditions have been changed during the course of the preceding cycle, the growth rate changes at this same point to a value proportional to the cell's new rate of mass increase. (3) The critical length, 2Λ , is twice the minimum theoretical length for cells. (4) Termination of chromosome replication, although necessary for subsequent cell division^{17,18}, does not control the change in rate of cell elongation.

A model consistent with these findings is that there is a minimum unit cell, of length Λ μm , which has a fixed number of sites of elongation (perhaps one). Growth in length of such a unit cell takes place at these sites, at a rate proportional to the number of sites, as well as to the growth rate in cell mass, until a new unit length has been completed (at a total length of 2Λ μm). At this point two things happen: septation is initiated between the two completed unit cells, and each of the two units begins to grow independently from new sets of growth sites.

The septation process, once initiated on the completion of the new unit, takes about 20 min to complete, independent of the growth rate. As a result, even though cells always initiate septation at a fixed length, the final length at the time of separation (and hence the average length of the population of cells) will be proportional to the growth rate. Thus, one of the oldest and simplest ideas about the control of cell division, namely that cells always begin to divide whenever they reach a certain critical size is, with minor modifications, seen to be consistent with our observations.

The rate at which each new unit cell grows would seem to be set at the time of its initiation. This rate is proportional to the growth rate in mass of the cell at the time it reaches length

Table 2 Rate of elongation of "preterminated" cells and control cells

Time (min)	Calculated ratio (termination theory)	Observed ratios	
		\bar{L}_p/\bar{L}_{c1}	\bar{L}_p/\bar{L}_{c2}
0	1.00	1.01	1.01
40	1.29	0.97	0.95
60	1.38	—	0.97
80	1.30	0.90	0.96

Ratios of mean cell lengths in synchronous cultures of *E. coli* K12 "M6K", a *leu⁻thyA⁻(dra⁻ or drn⁻)* derivative of MB93 A81 (ref. 23) growing at 30 °C in medium 3 (Table 1). Small cells were selected by sucrose gradient centrifugation²⁴ and either (1) reinoculated into the same medium (control 1) or (2) starved for leucine for 120 min to allow termination of chromosome replication^{16,20} before readdition of leucine and resumption of growth (preterminated cells) or (3) starved for both leucine and thymine for 120 min to prevent termination before readdition of both supplements and resumption of growth (control 2). Synchronous division took place at about 80 min after reinoculation into fully supplemented medium in all three samples. Mean cell lengths were measured at the indicated times after resumption of cell growth (\bar{L}_p for preterminated cells, \bar{L}_{c1} for control 1; \bar{L}_{c2} for control 2). The ratios of these lengths did not change significantly during the course of the experiments. The "calculated ratios" were based on the assumption that the rate of cell elongation would double at termination of chromosome replication. Termination in the control cells was assumed to take place 20 min before division. The maximum ratio of mean cell lengths would therefore be expected at 60 min. DNA synthesis was found to behave as expected, doubling once per cell cycle at the same time in both controls (following readdition of supplements), whereas it continued at the control rate for about 40 min in the leucine-starved cells and then stopped quickly. DNA synthesis in this sample, as expected, did not recommence immediately on readdition of leucine (although growth resumed immediately) but recommenced abruptly after about 20 more min.

2Λ (which is the time when the new sets of growth sites are supposed to be activated). Because the rate of mass increase responds immediately to changes in growth conditions, no matter at which stage of the cycle the change is made¹⁶, the volume of cells changes with growth rate in a way which is different from that which we describe here for cell length. Consequently, cell diameter increases with growth rate such as to accommodate the larger increase in volume than length^{6,7}. The different ways in which growth in mass and in length respond to changes in growth conditions provide an explanation for the observed proportions of cells at different growth rates and also results in the change from one set of proportions to the next being made within a single cell cycle of a change in conditions (see Figs 3 and 4).

Sargent⁸ has recently reported that for several theoretical models of cell growth the length of cells of *Bacillus subtilis* changes in a way which is consistent with a doubling in rate of elongation at a constant cell length that is independent of growth rate. From his data, together with some measurements of our own, we find that this length is also close to twice that calculated for "minimum cells" (zero growth rate) and, interestingly, that this value is very close to that estimated for *E. coli*. The large size, relative to *E. coli*, of *B. subtilis* cells in most growth media can therefore be ascribed entirely to the long duration of the septation process (estimated at about 1 h) in this organism. Sargent also reported that cells of *B. subtilis* change only in length, without change in diameter, at different growth rates⁸. This implies that, unlike *E. coli*, the rate of elongation per growth site is likely to change immediately after a shift in growth rate.

The model of cell growth presented here seems to be inconsistent with the observations on the variation in cell length and width as a function of thymine concentration in cultures of thymine-requiring auxotrophs of *E. coli*^{6,7}. As the thymine concentration is reduced, the replication time of the chromosome is increased, so that termination and cell division are delayed and thus average cell mass is increased. Our present model predicts that this increase in cell volume should be the result solely of an increase in cell length, but the reported measurements show that it is in fact largely due to an increase in cell width. This observation led to the suggestion that the rate of cell elongation is proportional to the number of chromosome termini per cell^{6,7}. Our results, however, show no such relationship. We do not know the reason for this apparent discrepancy.

In our model, septation and the activation of new growth sites take place at a fixed cell length, 2Λ . It is not implied however, that the trigger for these events is cell length *per se*. It may well be some correlated event, such as the completion of the required period of division protein synthesis¹⁶, which we have already suggested as the trigger for the initiation of the final septation process²⁰. But it is not possible to distinguish experimentally between the completion of a required period of protein synthesis and the attainment of the critical length as being the triggering event, because both are achieved at the same time and presumably involve similar biosynthetic reactions. The only correlated event which we have been able to eliminate is chromosome termination, because inhibition of DNA synthesis can be carried out specifically without immediately affecting cell growth. For the moment therefore, we can only point out the correlation and hope that further experiments will help to discover the proximate signal for the initiation of division.

We thank Millicent Masters and John F. Collins for advice.

Addendum: After this manuscript was submitted it came to our notice that N. B. Grover *et al.* have also measured cell length as a function of growth rate in *E. coli* with results which are indistinguishable from ours. They also conclude that their data agree with a model in which the rate of cell elongation doubles at about the time of chromosome termination.

All oxygens in nucleic acids react with carcinogenic ethylating agents

B. Singer

Department of Molecular Biology and Virus Laboratory, and Space Sciences Laboratory, University of California, Berkeley, California 94720

Over 80% of ethylnitrosourea and ethylnitrosoguanidine modification of nucleic acids is on oxygens. The reactivity of oxygens (other than ribose and phosphate) in single-stranded RNA is: O^2 of C > O^2 of U > O^6 of G > O^4 of U. In double-stranded DNA the order is: O^2 of T = O^6 of G > O^4 of T > O^2 of C. Oxygen reactivity of single-stranded DNA resembles RNA. The glycosidic bond of O^2 -alkylpyrimidines is labilised.

ALKYLATING agents of the general structure

are potent carcinogens which do not require metabolic activation. The most studied of this type of nitroso compound are *N*-methyl-*N*-nitrosourea (MeNU) and *N*-ethyl-*N*-nitrosourea (EtNU). Another group of carcinogens which are also highly mutagenic are also nitroso derivatives, the best known of which are *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG) and *N*-ethyl-*N'*-nitro-*N*-nitrosoguanidine (ENNG).

In recent years it has been found that the *N*-nitroso alkylating agents have an affinity for alkylating the oxygens of nucleic acids, in contrast to the "typical" alkylating agent (for example, dimethylsulphate) which is of low carcinogenicity or mutagenicity and which primarily alkylates ring nitrogens (reviewed by Singer, ref. 1). Following Loveless's suggestion that the O^6 of guanine could be alkylated in nucleic acids², a number of investigators did find that a significant proportion of the total alkylation was O^6 -alkyl G when nucleic acids were treated *in vitro* or *in vivo* with MeNU, MNNG and EtNU³⁻¹¹.

Due to the known lability of the alkyl group of O^6 -alkylguanosine, this derivative, and generally no other, was determined in enzyme digests of RNA rather than after hydrolysis with strong acid or base as customary for *N*-substituted derivatives. In DNA, either enzyme digestion or mild acid depurination was the method generally used to isolate that nucleoside or base without concomitant dealkylation. Singer and co-workers then found that enzyme digests of nucleic acids treated with MeNU or EtNU contained alkyl esters which were derived from alkylation of the internucleotide phosphodiester, and that alkyl phosphotriesters represented about two-thirds of the total bound alkyl groups in DNA and

RNA^{10,11}. Further examination of the alkyl products after enzyme digestion at neutral pH revealed that 10-15% of the alkylation of RNA by EtNU was on the ribose¹².

I now report that the newly described derivative, O^2 -ethylcytidine (O^2 -EtCyd)¹³, is a major product of neutral aqueous reaction of the single-stranded nucleic acids, TMV RNA and M13 DNA, with EtNU and ENNG. In double-stranded salmon sperm DNA this reaction is greatly suppressed and O^2 -ethylation of cytosine is only barely detectable. A further new finding is that both oxygens on uracil and thymine react with EtNU and ENNG. O^2 substitution of U in RNA and T in double-stranded DNA is greater than O^4 substitution, but in single-stranded DNA the O^2 and O^4 of T are equally reactive.

Techniques and their pitfalls

There are at least three reasons why *O*-alkylation of pyrimidines in nucleic acids has been overlooked until now. The first, and probably most important, is that one finds only what one looks for. Almost all of the *O*-alkyl pyrimidines have been prepared for the first time in this laboratory in the last year, and without authentic markers it is difficult to find and identify new products. Second, all *O*-alkyl pyrimidines are labile in acid and alkali so that losses (up to 100%) occur during the degradation of a nucleic acid unless neutral enzymatic digestion is used. Furthermore, separation of products in a digest must also be done under conditions which preserve the *O*-alkyl linkage. Third, mere coincidence of radioactivity with an ultraviolet absorbing marker in any system does not mean that the radioactive substance is completely or even partly identical with the marker.

The techniques used in this work which enabled us to avoid these pitfalls and to separate and quantitate the new derivatives discussed in this paper are all given in detail in preceding papers. Briefly they are: (1) the use of snake venom phosphodiesterase and phosphatases at pH 7.2 to digest alkylated polynucleotides and nucleic acids to nucleosides^{10-12,14,16}; (2) one-dimensional paper chromatography using butanol-ethanol-H₂O (80:10:25) (Solvent 1) to separate groups of possible products¹²⁻¹⁸; (3) additional separation techniques, for each group of possible products eluted from chromatograms, utilising the unique characteristics of the individual alkyl derivatives. For example, electrophoresis to separate products with different pK_a s^{15,16} or chromatography in borate-containing solvents to separate *O*-alkylnucleosides^{13,14}; (4) preparation and use as markers of all *N*- and *O*-monoethylated nucleosides¹⁰⁻¹⁸, and determination of their stability in conditions used for enzyme digestion, the R_f values in several neutral chromatographic systems, electrophoretic behaviour, rate of

acidic dealkylation, and so on; and (5) awareness of the fact that alkylation of pyrimidines in nucleic acids can diminish the stability of the glycosidic linkage.

Proof of formation of O^2 -ethylcytidine and O^2 -ethyldeoxycytidine

When alkylated single-stranded RNA, and poly(C) were enzyme-digested to nucleosides and chromatographed in a

neutral solvent, peaks of radioactivity co-chromatographed with authentic O^2 -ethylcytidine (Fig. 1) (data not shown for poly(C)). In the case of TMV RNA treated with EtNU or ENNG about 10% of the total radioactivity was in this area (A) (as shown in Fig. 1c and d), while with diethylsulphate (Et_2SO_4) reaction, no peak was exactly coincident with the marker (Fig. 1f) but about 2% of the radioactivity could be assigned to the marker area.

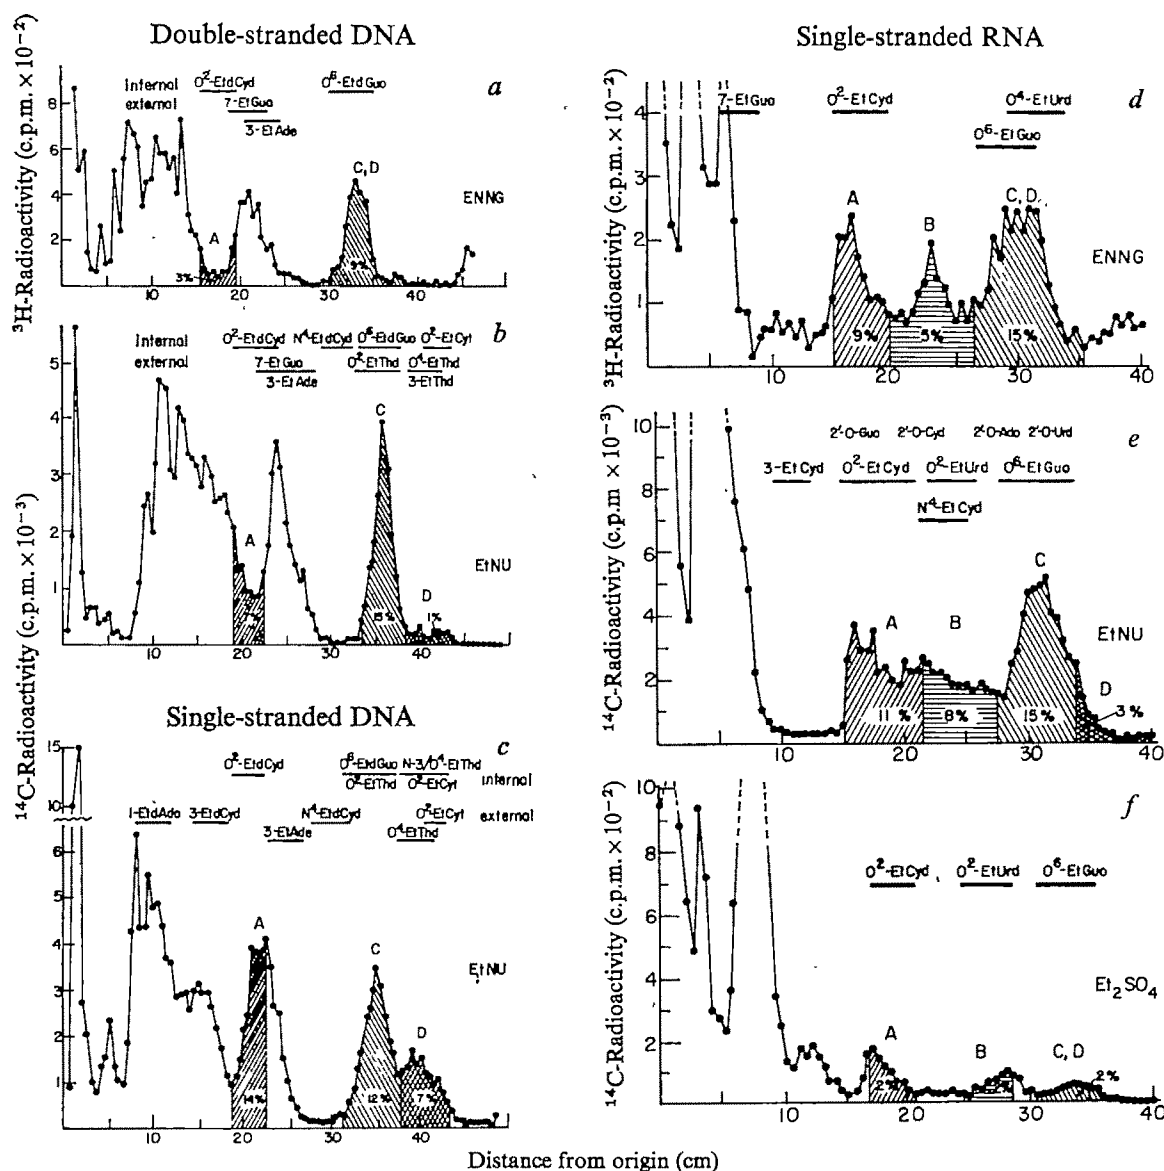

Fig. 1 Radioactivity profiles of chromatograms of enzyme digests of ethylated nucleic acids. 0.5–1 mg TMV RNA, salmon sperm DNA and M13 DNA were reacted in pH 6.1 or pH 7.3 cacodylate buffer 37 °C, 1–3 h, with ^{14}C -ethylnitrosourea (Farbwerke Hoechst AG, 4.1 Ci mol⁻¹) or ^3H -ethylnitrosoguanidine (Amersham/Searle, 110 Ci mol⁻¹) or ^{14}C -diethylsulphate (ICN, 4.09 Ci mol⁻¹). The methods are described in detail in earlier papers^{10,11}. After precipitating with ethanol until constant specific activity was obtained, the specific activity of ethylated nucleic acids varied from 20–400 c.p.m. μg^{-1} . The lowest extent of reaction was consistently obtained with ethylnitrosoguanidine. The percent alkylation with each reagent was very similar for RNA and DNA^{10,11}. Ethylated RNA (50–200 μg) was digested with snake venom phosphodiesterase, acid and bacterial alkaline phosphatases using method I described by Kusmierek and Singer¹⁴. 100–750 μg ethylated DNA in 0.1 M pH 7.2 Tris buffer containing 0.01 M MgCl_2 was digested with an equal weight of deoxyribonuclease, 37 °C, 4 h, then further digested with equal weights of snake venom phosphodiesterase, acid and bacterial alkaline phosphatases, 37 °C, 18 h. Singer and Kusmierek¹⁴ have reported that these neutral digestion conditions permit recovery of labile O -alkyl nucleosides and other alkylated nucleosides or bases such as 7-alkyl G and 1-alkyl A which are ring-opened and rearranged, respectively, at higher pHs. After adding ultraviolet-absorbing markers (prepared in this laboratory^{10–18,20}), digests of alkylated RNA or DNA were applied to Whatman 3MM and developed 16–20 h in butanol–ethanol–water (80:10:25). The positions of the marker nucleosides or bases were noted, and the entire paper was cut into 0.5-cm strips (to which were added 5 ml toluene containing 14.3 g Omnifluor/3 kg toluene) for radioactivity counting. Panels a–f are typical profiles and in each panel the type of nucleic acid and reagent are given. The bars above the chromatograms represent the ultraviolet-absorbing areas of each marker and in general the internal and external markers have the same R_f . In e the approximate positions of 2'- O -ethylnucleosides are also shown, based on their known R_f values¹⁴. O^2 -EtdCyd or O^2 -EtdCyt are termed 'A'; the area coinciding with O^2 -EtdUrd, 'B'; the area coinciding with O^2 -EtdGuo, 'C'; and the area coinciding with O^2 -EtdThd and O^2 -EtdCyt or O^4 -EtdUrd, 'D'. The percent of total radioactivity in each area is shown in the figures. After counting, paper strips from these and other areas were washed several times in toluene, dried and eluted with either water or methanol, then treated in various ways in order to separate the possible derivatives in each area (see text and Figs 2 and 4–6).

O^2 -EtCyd does not separate clearly in Solvent 1 from $2'$ - O -EtGuo or 1 -EtGuo, and peak A could contain these two derivatives. However, both Guo derivatives have a pK_a of ~ 2 (ref. 19) while O^2 -EtCyd has a $pK_a > 9.5$ ¹³. Consequently electrophoresis at $pH \sim 9$ was found to separate O^2 -EtCyd not only from derivatives of "low pK_a " but also from all other ethyl derivatives including those with a "high pK_a " such as 1 -EtAdo and 3 -EtCyd ($pK_a \sim 8.5$)¹⁹. Figure 2a illustrates that most of the radioactivity (from peaks dA and eA) coincides with O^2 -EtCyd upon electrophoresis in 0.1 M ammonium carbonate. The small peak of low pK_a was shown to be $2'$ - O -EtGuo ($\sim 1.8\%$ of total alkylation) when re-chromatographed in a borate-containing solvent¹⁴. Further proof that peak A was primarily O^2 -EtCyd was that the radioactivity from the high pK_a area of the electrophoresis (1) co-chromatographed with the marker and could be separated from 1 -EtGuo, the derivative with the closest R_f , by long chromatography in solvent 1 (Fig. 2b), and (2) the ^{14}C -labelled ethyl group was hydrolysed in N HCl at the same rate as the marker was dealkylated to cytidine.

The ethylation of the O^2 of dCyd in DNA was studied using double-stranded salmon sperm DNA and single-stranded M13 DNA. As seen in Fig. 1a and b, enzyme digests of ENNG and EtNU-treated salmon sperm DNA did not exhibit a peak of radioactivity co-chromatographing with O^2 -EtdCyd. The radioactivity, termed peak A, which really represented a minimum, was analysed using similar methods to those used to detect O^2 -EtCyd and it was found that O^2 -EtdCyd was less than 0.3% of the total radioactivity. The large peak moving slightly ahead of the marker O^2 -EtdCyd was identified by two-dimensional chromatography¹¹ as containing 7 -EtGua and 3 -EtAde (3:1); both bases were also in peak A and their presence illustrates the liability of the glycosidic bond of alkylpurine deoxynucleosides even at $pH 7.2$.

In studying the stability of the ethyl group in O^2 -EtdCyd (prepared from dCyd as described for the preparation of O^2 -EtCyd from Cyt¹³) it was found that heating in 0.1 N HCl at $70^\circ C$ for 30 min or at $pH 7.0$, $100^\circ C$ 1 h, caused complete depyrimidation without loss of the ethyl group and the product was O^2 -ethylcytosine (Fig. 3). These conditions are often

Fig. 2 Separation and identification of O^2 -EtCyd or O^2 -EtdCyd and O^2 -EtCyt. *a*, Superimposed radioactivity profiles of electrophoretograms of peak A from Fig. 1d and e (termed dA, eA). Material eluted from the O^2 -EtCyd area of EtNU- and ENNG-treated TMV RNA was separately electrophoresed in 0.1 M $(NH_4)_2CO_3$ ($pH \sim 9$)¹³. The electrophoretogram was cut in 101 cm strips and the radioactivity counted. The open circles are from dA and the closed circles from eA. The position of the internal O^2 -EtCyd for each electrophoretogram is similarly indicated. The mobility, at this pH , of O^2 -EtCyd was higher than any other ethylated nucleoside as shown by the separation of O^2 -EtCyd from 3 -EtCyd (pK_a 8.4) and 1 -EtAdo ($pK_a \sim 8.5$)¹⁹. *b*, Superimposed radioactivity profiles of a portion of chromatograms of the material co-electrophoresing with O^2 -EtCyd in *a*. After elution, samples were chromatographed in the same solvent as in Fig. 1 except that the chromatogram was developed 48 h. O^2 -EtCyd was internal while 1 -EtGuo and Ade were used as external markers since with 16–20 h chromatography these derivatives do not separate from O^2 -EtCyd (data not shown) while with longer development their movement differs. *c*, Radioactivity profile of an electrophoretogram of peak A from Fig. 1c (termed cA). Material eluted from the O^2 -EtdCyd area of EtNU-treated M13 DNA was electrophoresed in 0.1 M $(NH_4)_2CO_3$ ($pH \sim 9$). O^2 -EtdCyd is completely separated from 3 -EtAde (pK_a 6.5) and 3 -EtdCyd (pK_a 8.5) as well as all derivatives with a $pK_a < 6.5$. The radioactivity co-electrophoresing with O^2 -EtdCyd had the same acid stability as the marker. *d*, Radioactivity profile of a silica gel thin-layer chromatogram of peak D from Fig. 1c (termed cD). This peak from EtNU-treated M13 DNA which contained ultraviolet-absorbing markers of O^2 -EtThd, 3 -EtThd and O^2 -EtCyt was developed in acetone-benzene (2:1), then cut in 0.5 cm strips and the radioactivity counted.

Fig. 3 Ultraviolet absorption spectra of O^2 -ethylcytosine at pH 1 (---) and pH 6-13 (—). The absorption maxima are given in the figure. O^2 -Ethylcytosine was prepared by the following method. To 30 mg cytosine in 10 ml methanol was added a solution of diazoethane in ether prepared according to the procedure of Robins *et al.*³² for the preparation of diazomethane (solution A). Several additions of several millilitres each were needed to saturate the solution. The ether was evaporated off and the remaining solution chromatographed on Whatnam 3MM in butanol-ethanol-water (80:10:25) to separate the several derivatives. O^2 -Ethylcytosine has in this system an R_f 0.88 and moves ahead of all other ultraviolet absorbing compounds. The yield from 30 mg cytosine is about 300 absorbancy units. O^2 -methylcytosine was prepared with a lesser yield using diazomethane. The methyl derivative, obtained by a different method, has been described by Sukhorukov *et al.*³⁴, although the second λ_{max} (228 in acid and 223 in alkali) was not shown by them probably due to impurities in their sample. The reported pK_a of O^2 -methylcytosine is 5.41 (ref. 36).

used for depurinating alkylated DNA and would be likely to depyrimidate O^2 -EtdCyd. Since a substantial proportion of 7-EtdGuo and 3-EtdAdo was depurinated during pH 7.2 enzyme digestion, it seemed reasonable to suspect that, in addition to 7-EtGua and 3-EtAde, O^2 -EtCyt would also be present and by R_f would be in peak D. This was shown by electrophoresis of peak D (Fig. 1c) at pH 5.5, where O^2 -alkylcytosine which has a reported pK_a of 5.4 (ref. 19) migrates while the other possible products, O^4 -EtThd and 3-EtThd, do not move at this pH. Although O^2 -EtCyt could be identified, the amount was extremely low.

Identification of O^2 -EtdCyd and O^2 -EtCyt was unequivocal in EtNU-treated single-stranded M13 DNA. First, although peak A (Fig. 1c) was not completely coincident with O^2 -EtdCyd, the radioactivity sharply increased in the area of the marker,

rather than decreasing as was the case for double-stranded DNA. Electrophoresis at pH ~9 of the shaded area in peak A clearly resolved O^2 -EtdCyd from other possible neighbouring ethyl nucleosides of pK_a 6.5 and pK_a ~8.5 (Fig. 2c), and there was a distinct peak of radioactivity co-electrophoresing with the authentic nucleoside. On the basis of earlier experiments it was expected that O^2 -EtCyt would also be formed as a result of depyrimidation during enzyme digestion. Peak D contained as internal markers O^2 -EtThd, 3-EtThd and O^2 -EtCyd, which were resolved by silica gel thin layer chromatography. A distinct and sharp peak of radioactivity coincided with O^2 -EtCyt (Fig. 2d) and other similarly sharp peaks were found with the other two markers.

Proof of formation of O^2 - and O^4 -ethyluridine and O^2 - and O^4 -ethylthymidine

The R_f of O^2 -EtUrd in the chromatographic system used in Fig. 1 is very similar to the R_f s of 2'- O -EtCyd and N^4 -EtCyd and the peak from RNA digests designed as 'B' in Fig. 1d-f could contain all three derivatives. Similarly, O^4 -EtUrd is coincident with 3-EtUrd (peak D) and not completely separable from O^6 -EtGuo and 2'- O -EtUrd (peak C) (Fig. 1d-f). Several techniques were used to resolve the derivatives in peaks B, C and D; the most useful of these were electrophoresis in pH 3.0 sodium citrate to separate O^2 -EtUrd (pK_a < 1) from N^4 -EtCyd and 2'- O -EtCyd (pK_a ~4.2)¹⁹ and thin-layer chromatography²⁰ which can separate O^4 -EtUrd from O^6 -EtGuo, 3-EtUrd and 2'- O -EtUrd in peaks C and D. Figures 4b and 5b illustrate these separations. The areas of radioactivity co-chromatographing with O^4 -EtUrd (shaded area of Fig. 4b) and co-electrophoresing with O^2 -EtUrd (shaded area of Fig. 4a) were each eluted and in both cases all radioactivity was volatilised after treatment with N HCl (100 °C, 60 min) and the ultraviolet-absorbing markers were converted to uridine, thus confirming that the original derivatives were oxygen substituted.

O^2 -EtThd has the same R_f as O^6 -EtdGuo (peak C) (Fig. 1a-c) and the two nucleosides also behave similarly in that both lose their ethyl group upon hydrolysis in N HCl at 100 °C, 60 min. However, thin-layer chromatography²⁰ clearly separates them (Figs 5a and 6a) as well as O^4 -EtThd and 3-EtThd which are mainly in peak D (Fig. 6b). Thin-layer chromatography of

Table 1 Proportion of ethyl products from hydrolysates of nucleic acids reacted with ^{14}C -ethylnitrosourea

Derivative	TMV RNA	M13 DNA	Salmon sperm DNA
Total ethylation* (%)			
O^6 -EtGuo or O^6 -EtGuo	5†	7	7‡
O^2 -EtUrd	7		
O^2 -EtThd		5	6
O^4 -EtUrd	3		
O^4 -EtThd		5	1.4
O^2 -EtCyd	8		
O^2 -EtdCyd + O^2 -EtCyt		3	0.5
Total	23%	20%	15%
2'- O -EtAdo, -Guo, -Cyd, -Urd	12±2§	—	—
Ethylphosphotriester	65¶		70
N-Ethyl	16		17

*See Fig. 1 for methods. The per cent ethylation in different experiments varied from 0.5 to 1.5%.

†Singer and Fraenkel-Conrat¹⁰ reported 12% O^6 -EtGuo on the basis of coincidence of radioactivity with the authentic marker and volatility of most of the ethyl groups in N HCl 100% 1 h. The present data show that this peak also contains O^4 -EtUrd and 2'- O -EtUrd.

‡Sun and Singer¹² reported 12% O^6 -EtGuo on the same basis as footnote †. The present data, if O^2 -EtThd and O^6 -EtdGuo are added, give a similar value for this peak.

§Data from Singer and Kušmirek¹³.

¶Data from Singer and Fraenkel-Conrat¹⁰. The amount of esterification was determined by distillation of ethanol after N HCl hydrolysis. Ethanol calculated to be derived from O^6 -EtGuo was subtracted. If now the volatile ethyl groups on the uridine ring are subtracted as well, the calculated amount of riboalkylphosphotriester is about 54%.

||Data from Sun and Singer¹².

combined peaks C and D further illustrates these separations (Fig. 5a). One additional proof of the identity of O^3 -EtThd is the great instability of both the alkyl and the glycosidic bond²⁰; thus hydrolysis in 0.1 N HCl at 70 °C for 30 min almost quantitatively converts this derivative to thymine, while O^6 -EtdGuo is only depurinated, becoming O^6 -EtGua.

O^4 -EtThd and 3-EtThd (peak D) do not separate from O^2 -EtCyd in solvent 1 although the R_f s are somewhat different (Fig. 1b and c). They all separate completely upon thin-layer chromatography, with O^2 -EtCyt moving ahead of the other derivatives (Fig. 2d). In addition, O^2 -EtCyt ($pK_a \sim 5.4$) can

basis of its symmetry and sharpness, contains two major and one minor component (Fig. 6a).

There are two points to be noted before quantitative conclusions are drawn from the data on the figures and Table 1. First, although the alkylated nucleic acids were digested for long periods of time with large amounts of enzymes, from 10 to 40% of the total radioactivity remained at the origin. This material, which was not due to generally incomplete digestion since there was no associated ultraviolet absorbancy, did not elute from the paper even with 0.1 N HCl or long incubation at 37 °C. Since the origin material is labelled, it obviously

Fig. 4 Separation and identification of O^2 -EtUrd and O^4 -EtUrd. *a*, Radioactivity profile of an electropherogram of peak B from Fig. 1e (termed eB). Material eluted from the O^3 -EtUrd area of EtNU-treated TMV RNA was electrophoresed in 0.1 M pH 3 sodium citrate buffer. O^3 -EtUrd does not migrate at this pH while nucleosides which also could be in peak B, for example, N^4 -EtCyd, move very far. *b*, Radioactivity profile of a silica gel thin-layer chromatogram of peak D from Fig. 1e (termed eD). Material eluted from the O^4 -EtUrd area of EtNU-treated TMV RNA, which also contained a marker of 3-EtUrd, was chromatographed using benzene-acetone (2:1). See Fig. 5b for separation of O^4 -EtUrd from O^6 -EtGuo, $2'$ - O -EtUrd, and 3-EtUrd.

be separated from the thymidine derivatives by electrophoresis in pH 5.7 formate buffer.

Quantitative aspects of *O*-ethylation

In Fig. 1, the percentages given in shaded areas A–D refer to percentage of total recovered radioactivity. In the case of RNA treated with ENNG or EtNU, most of the radioactivity in these areas could be assigned to a known *O*-alkyl derivative. Thus peak A is essentially O^3 -EtCyd (Fig. 2), peak B is about half O^2 -EtUrd (Fig. 4a), peak C contains O^6 -EtGuo and $2'$ - O -EtUrd while peak D is O^4 -EtUrd (Fig. 4b and Fig. 5b). Diethylsulphate-treated RNA (Fig. 1f) was very low in all these derivatives and none of these peaks contained more than 0.5% (of the total radioactivity) of an identifiable derivative. Nevertheless, O^3 -EtCyd was identified in peak A and O^6 -EtGuo and O^4 -EtUrd in peaks C, D.

EtNU-treated single-stranded DNA resembled EtNU-treated single-stranded RNA in the chromatographic profile and about 10% of peak A (Fig. 1c) is O^2 -EtdCyd (Fig. 2c). Peak C is about 40% O^2 -EtThd, 55% O^6 -EtdGuo and the remaining 5% is O^4 -EtThd coming from peak D where it is a major component. Peak D comprises 70% O^4 -EtThd, 24% O^2 -EtCyt and 6% 3-EtThd.

Area A of EtNU- and ENNG-treated salmon sperm DNA (Fig. 1a and b) contains primarily N-ethyl products with a trace of O^2 -EtdCyd. Peak C is almost equally divided into O^3 -EtThd and O^6 -EtGuo (Fig. 6a) while peak D is mostly O^4 -EtThd (Fig. 6b). It also can be seen that neither O^4 -EtThd nor O^4 -EtUrd is totally separated from peak C. Another, and more important, fact to be noted, is that a peak, such as C in Fig. 1b, which might be surmised to be homogeneous on the

represents bound alkyl groups and cannot be disregarded. But at this time I have no further information. (One possibly pertinent point is that alkylated poly(U) and poly(C) are almost completely digested using the same enzymes as judged by the fact that less than 5% of the radioactivity is at the origin.) All percentages of known derivatives are based on total radioactivity on the paper and do include the origin. Consequently it is possible that any derivative may remain partly in an enzyme-resistant oligonucleotide at the origin.

Second, *O*-alkyl derivatives are relatively labile and particularly in the case of DNA the percentage of O^2 -EtThd and O^3 -EtdCyd should be taken as minima since these two derivatives are depyrimidated easily and may be lost during reaction.

Given these caveats, Table 1 presents data for EtNU-treated nucleic acids, averaged from several experiments, which show that O^3 -EtUrd or O^3 -EtThd is a major derivative in EtNU-treated TMV RNA, salmon sperm DNA and M13 DNA. O^4 -EtUrd or O^4 -EtThd is formed in lesser amounts but still exceeds the amount of most N-ethyl derivatives. O^3 -EtCyd is formed to a greater extent than O^6 -EtGuo in EtNU- or ENNG-treated TMV RNA. Formation of this derivative is suppressed in double-stranded DNA but when the DNA is single stranded, considerably more reaction takes place. Data for the alkylation products of ENNG-treated nucleic acids are very similar and are not given in tabular form.

A summary of the relative reactivity of various sites in single- and double-stranded nucleic acids treated with EtNU or ENNG is as follows:

Double-stranded DNA:

Phosphate > N^7 -G > O^3 -T, O^6 -G, > N^3 -A > O^4 -T > O^2 -C, other N-

Single-stranded RNA:

Phosphate > Ribose, $N7-G > O^2-C > O^2-U, O^6-G > O^4-U > N1-A, N3-C > \text{other } N$

The two homo-polynucleotides which were treated with the same reagents are also modified primarily on the oxygens and the data are given below for comparison. The work on poly(U) is published separately¹⁴ but the data for poly(C) are from the present series of experiments.

Poly(U): Phosphate > $O^4 > O^2$, Ribose > $N3$

Poly(C): $O^2 > N3, N^4 > \text{Phosphate} > \text{Ribose}$

We have routinely in the recent past used $NHCl$ volatility as a semi-quantitative test for O -alkylation in RNA and $HClO_4$ volatility for O -alkylation in DNA. The alkyl groups of all of the derivatives discussed in this paper are hydrolysed by the HCl treatment except for ribose alkyl nucleosides which require $HClO_4$. Therefore those alkylating agents which do not with acid yield an alcohol may rather safely be presumed not to modify oxygens significantly. As an example, Singer and Fraenkel-Conrat¹⁰ reported 1% ethanol upon HCl hydrolysis of Et_2SO_4 -treated RNA and now Fig. 1f illustrates that little O -alkylation of pyrimidines occurs, thus serving to validate analytical data obtained with alkylsulphate and alkylalkanesulphonates before our knowledge of O -alkylation of pyrimidines^{10,11}.

Possible biological consequences of O -alkylation

The study of the alkylation of nucleic acids started from the observations that alkylating agents such as mustard gas were

inactivating to DNA containing viruses²¹ and that mustard gas was mutagenic²². The principal site of reaction with mustard gas and many other alkylating agents was found to be the $N7$ of guanine¹ and from then on the presence of 7-alkylguanine was presumed to be the significant event in causing a biological effect. Since alkylation of the $N7$ did not change the base-pairing properties of $G^{23,24}$, its effects in DNA were generally attributed to the rapid depurination of 7-alkyl G which further led to chain breakage by β -elimination.

As time went on the simple relationship between the amount of 7-alkylguanine and biological change eroded. This became particularly apparent when alkylation-induced carcinogenesis was studied and ethylating agents were more carcinogenic in rats than the analogous methylating agents while the amount of 7-ethyl G was a small fraction of the amount of 7-methyl G¹.

When the highly carcinogenic N -nitroso compounds were used to modify nucleic acids *in vitro* or *in vivo* another derivative was found, O^6 -alkylguanine, which represented a few per cent of the total alkyl groups³⁻¹¹. When reactions were performed with alkylating agents of low carcinogenicity, this derivative was not detected or was present in trace amounts^{3,4,6,10,11,25}. Thus the effects of the presence of O^6 -alkylguanine became of prime interest since there seemed to be a correlation between its formation and the carcinogenicity of the alkylating agent. In contrast to 7-alkyl G, O^6 -alkyl G in polymers has been shown to mispair²⁴ and thus could be considered mutagenic. There is also good evidence that there is an enzymatic excision of O^6 -alkyl G from DNA²⁶ and in rats given MeNU or EtNU under conditions where only brain tumours develop, O^6 -alkyl G is removed from the brain very much more slowly than from

Fig. 5 Separation and identification of O^6 -EtdGuo, O^2 -EtThd and O^4 -EtThd from DNA and the corresponding ribo derivatives from RNA. Radioactivity profile of silica gel thin-layer chromatograms developed with benzene-acetone (2:1). The positions of internal ultra-violet absorbing derivatives are shown by arrows. *a*, Combined peaks C, D from Fig. 1a (termed *aCD*). This material from ENNG-treated salmon sperm DNA contained internal markers of O^2 -EtThd, O^4 -EtThd, O^6 -EtdGuo and 3-EtThd. *b*, Combined peaks C, D from Fig. 1d (termed *dCD*). This material from ENNG-treated TMV RNA contained internal markers of O^4 -EtUrd, O^6 -EtGuo, 3-EtUrd and 2'-O-EtUrd.

other tissues which do not develop neoplasms^{8,9,27-31}. It can be postulated that neoplasms develop in the brain because O^6 -alkyl G remains in the DNA and mispairing occurs.

The same reagents which alkylate the O^6 of G have been shown in this paper to react with all oxygens of the pyrimidines (Table 1). In quantitative terms the O^3 of T in double-stranded DNA reacts to the same extent as does the O^6 of G. Since the alkylation of the O^3 position of T greatly labilises the glycosidic linkage, it is likely that O^3 -alkyl T may depyrimidinate spontaneously or enzymatically leaving a gap which may or may not

or translation. Whether carcinogenesis can be explained solely in terms of mutation is doubtful since mutation is a frequent event and easily produced in cells while carcinogenesis is rare and not yet a test-tube phenomenon.

In conclusion, the *N*-nitroso alkylating agents are powerful carcinogens and alkylate all oxygens in nucleic acids. Other alkylating agents of lesser carcinogenicity do not have an affinity for oxygens. It is tempting to hypothesise that the carcinogenicity of an alkylating agent can be assessed by its reactivity towards oxygens, but I believe this is still premature.

Fig. 6 Separation and identification of O^6 -EtdGuo, O^2 -EtThd and O^4 -EtThd. Radioactivity profiles of silica gel thin-layer chromatograms developed with benzene-acetone (2:1). Peaks C and D, from EtNU-treated salmon sperm DNA (termed 2C and 2D) were separately chromatographed. The position of the internal ultraviolet-absorbancy derivatives are shown by bars or arrows. *a*, Peak *bC* containing internal markers of O^2 -EtThd, O^4 -EtdGuo and 3-EtThd. See Fig. 5, left panel, for a similar chromatogram of combined peaks C and D.

be repaired. In O^2 -alkyl U or T there is no proton at the *N*-3 which means that normal base-pairing with A cannot occur.

Alkylation of the O^4 of U or T may also lead to mispairing since these derivatives also cannot pair normally to A but instead may tend to base pair with G and thus be considered pro-mutagens. While the amount of O^4 -EtThd is relatively low in double-stranded DNA, it is considerable in single-stranded nucleic acids. This is perhaps the place to emphasise that the study of alkylation of "double-stranded" DNA must also consider that replicating DNA contains single-stranded segments and this portion of the molecule will react in a similar manner to any single-stranded polynucleotide, be it RNA or DNA.

The O^3 of C in double-stranded DNA is quite unreactive but in single-stranded DNA the reactivity is greatly increased, and in RNA the amounts of O^3 -alkyl C exceeds that of any derivative modified on the base. This modification in DNA destabilises the glycosidic bond and even with the most gentle handling, half of the derivative is found as the base, O^3 -ethylcytosine. This readiness to depyrimidinate may be occurring continually in the cell with the effect of creating deletions. In RNA where the glycosidic linkage is stable, O^3 -alkylation of C forms a quaternary structure and it is predicted that there will be random mispairing of bases.

Two other significant oxygen alkylations by *N*-nitroso compounds should be mentioned although they are the subjects of separate papers. In RNA ribose is alkylated¹², a modification which may affect mRNA function, and in both DNA and RNA alkyl phosphotriesters are formed (50–70% of all alkylation)^{10,11} which we have shown to be lethal³². Thus all types of alkylation of a nucleic acid are likely to have biological consequences.

These are probably all related in some way to genome mutation or messenger alteration, that is, a change in transcription

I would like to acknowledge the contributions of my collaborators, Drs L. Sun and J. T. Kuśmierk, in much of this work. Dr H. Fraenkel-Conrat has been a constant source of advice and criticism.

letters to nature

Direct test of the constancy of fundamental nuclear constants

THE possibility that fundamental nuclear constants may vary slowly while the Universe expands has been discussed by several authors¹⁻⁵. I try here to show that the well known resonance properties of the 'heavy nucleus plus slow neutron' system make it a sensitive 'receiver', sharply tuned to the current values of nuclear constants.

What are the restrictions, imposed by experiment that during the time interval ΔT the resonance energy shift had not exceeded ΔE_{exp} ? Simple estimates of residual interaction matrix elements suggest that for the overwhelming majority of compound nucleus resonances one should expect their shifts to be not less than the single-particle resonance shift ΔE_0 . The latter is connected with the relative change in strong coupling constant g_s ,

$$\frac{\Delta E_0}{V_0} \approx \frac{\Delta g_s}{g_s} \quad (1)$$

where V_0 denotes the depth of the nuclear potential well. Assuming $dg_s/dt = \text{constant}$, we get a restriction

$$\frac{1}{g_s} \left| \frac{dg_s}{dt} \right| \lesssim \frac{1}{\Delta T} \frac{\Delta E_{\text{exp}}}{V_0} \quad (2)$$

The positions of many low lying resonances have been known to an accuracy of 10^{-3} eV for quite a time⁶. Assuming $V_0 \approx 50$ Mev (ref. 7) and $\Delta T \approx 10$ yr we derive

$$\frac{1}{g_s} \left| \frac{dg_s}{dt} \right| \lesssim 2 \times 10^{-13} \text{ yr}^{-1} \quad (3)$$

which is the same result as that established by Davies on the basis of Dyson's cosmological argument⁵.

The Coulomb force increases the average internucleon distance by $\sim 2.5\%$ for $A \approx 150$ (ref. 7). Thus we obtain an estimate for the Coulomb coupling constant α 20 times higher than

Table 1 Comparison of upper bounds of the variation of nuclear constants

	Dyson, Davies	Present work
$1/g_s dg_s/dt (\text{yr}^{-1})$	2×10^{-13}	5×10^{-13}
$1/\alpha d\alpha/dt (\text{yr}^{-1})$	2×10^{-14}	10^{-17}
$1/g_w dg_w/dt (\text{yr}^{-1})$	10^{-10}	2×10^{-13}

from equation (2). The weak interaction contribution to the total energy of the nucleus is $\sim 10^{-8}(\mu/m)^2$, where μ and m are the pion and nucleon mass, respectively⁸. The upper bound on the time variation of the weak coupling constant g_w is therefore 5×10^6 times higher than for g_s .

The low lying resonance parameters determine the capture cross section for slow neutrons. So data on thermal cross section values in the remote past are of great interest. The recently discovered traces of ancient (1.8×10^9 yr old) natural nuclear reactors in the uranium deposits of Oklo (Gabon, West Africa)^{9,10} have proved to be important in this respect.

The isotopic composition of Sm and Eu has been measured¹¹ for samples in the reactor core, irradiated by an independently determined¹² integrated flux of thermal neutrons $\Phi t \approx 10^{21}$ neutrons cm^{-2} . Given Φt and fission yields one can determine the capture cross-section values $\approx 1.8 \times 10^9$ yr ago. Three standard deviations give the possible range of the cross-section variation, which is connected with the resonance energy shift through the Breit-Wigner formula. One is thus led to the restriction $|\Delta E_{\text{exp}}| \lesssim 0.05$ eV, and to the estimates of the upper bounds on the variation of fundamental nuclear constants shown in Table 1 along with the earlier limits of Dyson and Davies.

These estimates seem to exclude all variants of nuclear constants change based on Dirac's 'Large Numbers Hypothesis'¹. It is, however, desirable to obtain as strict bounds on ΔE_{exp} as possible. Precise measurements of the isotopic shifts for all rare-earth fission products in the reactor core are desirable in this respect.

I would like to express my gratitude to V. E. Bunakov, V. N. Efimov, A. N. Erykalov, V. A. Ruban, and especially to Yu. V. Petrov for discussions and comments.

Why measure astrophysical X-ray spectra?

MANY of the interesting results of X-ray astronomy such as the presence of compact sources in close binary systems, have been derived from light curve studies¹, obtained with quite simple detectors. On the other hand, a high resolution spectrometer, one of the most sophisticated pieces of instrumentation, is almost invariably included in solar X-ray satellites, and is used increasingly in cosmic studies². Here we wish to stress that even spectra of the highest resolution are of limited applicability in many important astrophysical problems and also perhaps to indicate the value of cost-effective planning of expensive instrumentation in general.

In addition to providing useful data through measurements of Doppler shifts and line profiles, a prime aim of high resolution spectrometry is the inference of source structure in terms of

temperature distribution of thermal particles³⁻⁶ or energy distribution of non-thermal particles⁶. These distributions are fundamental to our understanding of source mechanisms since they define both the total energy requirements⁷ and the role of energy transfer mechanisms such as conduction⁸. In this respect the X-ray spectrum problem is equivalent to optical/ultra-violet spectral studies of the solar (and stellar) chromosphere-corona structure. The thermal problem is that of the emission from an optically thin non-isothermal atmosphere and may be expressed as^{3,5,7,8}

$$I(\epsilon) = \int_T \xi(T) F(\epsilon, T) dT \quad (1)$$

where $I(\epsilon)$ is the X-ray flux at energy ϵ , $F(\epsilon, T)$ is the emission function at a temperature T per unit emission measure of a plasma of cosmic abundances⁴, and $\xi(T)$ is the emission measure of the source, differential in temperature and normalised for the source distance.

We emphasise at the outset that this equation, and its limitations discussed below, is common to spectrometry of all plasma—solar, cosmic and laboratory.

Mathematically we have to find $\xi(T)$ from $I(\epsilon)$ by inversion of equation (1) which is a Fredholm integral equation of the first kind. Such problems are mathematically ill posed¹⁰. This is distressing since it means that very small changes in $I(\epsilon)$ produce very large changes in ξ . Alternatively, a vast range of ξ 's is capable of reproducing the spectrum within arbitrarily small observational errors.

In practice of course, $I(\epsilon)$ can only be specified at a finite number of points, say n lines or continuum intervals. Given the data vector $Y = \{I(\epsilon_i)\}$ the simplest approach then seeks to find a discrete approximation X to $\xi(T)$ which satisfies

$$AX = Y \quad (2)$$

with $X = \{\xi(T_j) \Delta T_j\}$ where the T_j ($j = 1-n$) are a suitably chosen temperature grid and $A = \{F(\epsilon_i, T_j)\}$ is the matrix representation of the emission function. The required solution can be found by direct inversion

$$X = A^{-1}Y \quad (3)$$

To illustrate the practicalities of this apparently simple situation we now consider the analysis of solar active regions (AR). Attempts to use equation (3) directly for AR analysis using five or more X-ray resonance lines have run several authors^{11,13} into difficulties with nonsensical solutions, that is negative emission measures. Disregarding this salutary warning sign, 'analyses' have been tried to elude the inversion problem by fitting a trial function for X to the data. In all published AR (and solar flare) models^{11,13-17} the fitting function has been chosen purely for expediency, without any physical foundation. In addition, the results are invariably published without proper error analysis and without due consideration of the uniqueness of the model. We now examine these points in detail for a typical active region computation.

Figure 1(a) shows an AR model of the best-fit type¹¹. (This might equally be a cosmic X-ray source model (ref. 12). Using equation (2) we evaluate the fluxes, Y , to be expected in the 5 lines on which this model was based. To test the accuracy (stability) with which X can be derived from these fluxes we perturb the elements of Y with up to 5% random errors so generating a new set \hat{Y} of fluxes, and reinvert by equation (3) to obtain the corresponding new derived structure $\hat{X} = A^{-1}\hat{Y}$. Figure 1b-d show three random realisations of this procedure, and it can be seen that none of these remotely resembles the true structure Fig. 1a. The essential fact is, however, that any of the structures in Fig. 1 (and innumerable others) would reproduce the observed X-ray spectrum to better

than 5%—well within the data accuracy. Had models^{11,13} been published with such an error analysis it would have been immediately clear that their 'best fit' structures were so non-unique as to be physically useless. It follows likewise that models based on minimum χ^2 or other fitting procedures with totally empirical fitting functions containing several adjustable parameters¹⁴⁻¹⁷, are physically meaningless, since an extremely wide range of functions would yield an excellent fit to the data.

Physically this analysis means that the emitted spectrum has a very low sensitivity to any features of source temperature structure other than its crudest nature—for example mean

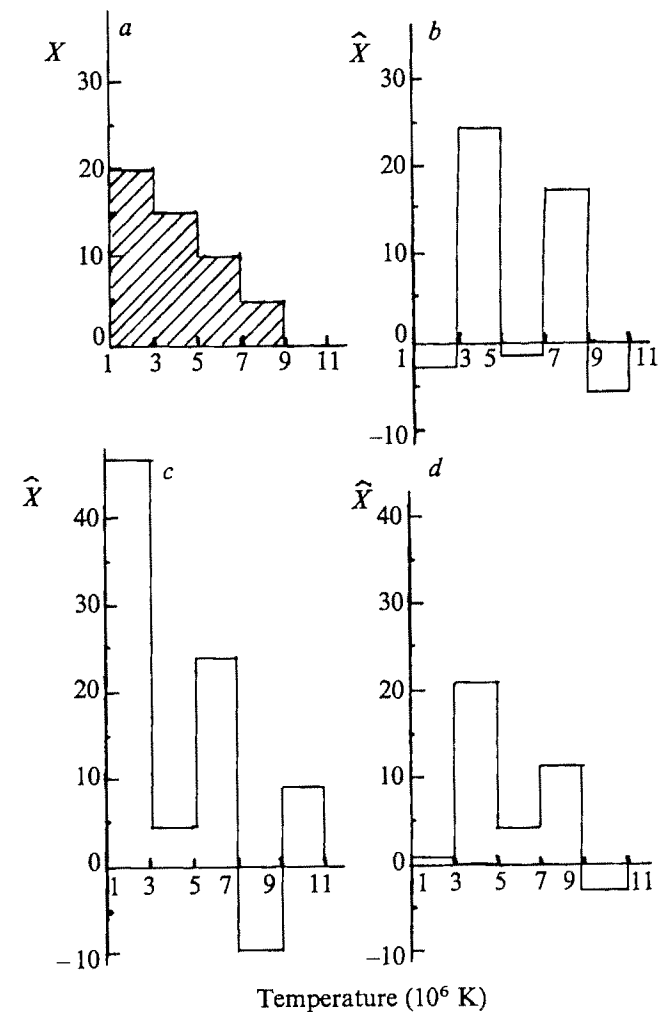

Fig. 1 a, A model (discretised) source temperature structure $X(T)$ which has a spectrum comparable to that observed in ref. 11 and satisfying the constraints they put on $X(T)$. b, c, d, Random realisations of the solutions X obtained on randomly-perturbing the spectral data by up to 5%.

temperature and variance. Theoretically, this result could have been anticipated long before the launch of any instruments. The essence of the problem is that the kernel function F in equation (1) is very flat in temperature (for both lines and continuum) which always leads to severe instability in equations of this type. Alternatively, in matrix form, equation (2), it is readily shown⁸ that errors in \hat{Y} can be magnified in the solution \hat{X} by factors up to η , the condition number of A . (For infinite temperature sensitivity in F , A is diagonal and $\eta = 1$, while for zero sensitivity η is infinite.) For the 5 line analysis quoted above we found $\eta \approx 30$ which explains the nonsensical solutions in Fig. 1 since the errors in \hat{X} can be as large as $30 \times 5\% \approx 150\%$. It should be emphasised that this difficulty cannot be overcome merely by choice of different spectrum lines since all line responses, being governed by excitation from the

Maxwellian electron distribution, contain the factor $\exp(-\varepsilon/kT)$ which is the root of the ill-conditioning of equation (1).

Although the stability problem discussed above is well recognised in other branches of physical science^{18,19} it has so far been neglected in the field of X-ray astronomy. Here, however, the inversion problem is particularly important since knowledge of plasma temperature structure has a direct bearing on other applications of X-ray spectra. For example, computations of element abundance (and also oscillator strengths) are always based on some assumption relating the temperature structure of the source to the temperature sensitivity of lines¹⁷. Thus such methods cannot be decoupled from the difficulties presented here.

In conclusion we emphasise that these snags are not restricted to the inference of thermal structure for solar and cosmic plasmas; they also arise in non-thermal source analysis²⁰. While we agree that limited information on source structures can be obtained from spectral observations, our analysis indicates that such rudimentary information may well be obtained with instrumentation of much lower resolution than is currently available¹⁸. It is vital therefore, in assessing the cost-effectiveness of further X-ray instrumentation, to base future experiments on sound analysis of what is scientifically possible rather than on what is technologically feasible. We therefore recommend a much greater degree of theoretical sophistication in planning satellite experiments since the problem of ill-conditioning, and hence the potential ill-conception of experiments, is indeed universal in physical modelling from data.

We would like to acknowledge the support of a research grant from the SRC.

Periodic behaviour of the X-ray flux from the region near 3U1727-33

THE MSSL 2.5–7.5 keV X-ray detector onboard Copernicus¹ was pointed in the vicinity of 3U1727–33 for a total of ~6 h on April 14, 1973 (ref. 2). The $2.5^\circ \times 3.5^\circ$ f.w.h.m. field of view of the detector included the positions of MXB1730–335 (ref. 3), MXB1728–34 (ref. 4) and 3U1727–33 (ref. 5). A new position for 3U1727–33 has been communicated by Saulson and Forman (unpublished). The revised error box is smaller than the one reported in ref. 5 and includes the position of MXB1728–34. The background subtracted count rate observed by Copernicus has been plotted in Fig. 1. Each bin represents one 63-s accumulation followed by 24 s of dead time. The gaps in the data are caused by the occultation by the Earth of the source and passage of the satellite through high back-

ground regions. It is clear from Fig. 1 that the flux is modulated throughout with a period of ~8 min. Using the power spectrum analysis technique described in ref. 6, we find a period of 7.90 ± 0.03 min, with a probability that this could arise from random noise of 10^{-17} and an average modulation amplitude of $23 \pm 5\%$ of the mean flux. Because of the finite sampling time (86.509 s) we cannot exclude the possibility that we are observing an alias of a modulation shorter than the Nyquist frequency of the data. Table 1 gives the first four periods which alias to 7.9 min,

Table 1 Possible aliases to 7.90 min

min	s	Attenuation
7.90 ± 0.05	474.0 ± 3.0	0.97
1.764 ± 0.003	105.84 ± 0.18	0.52
1.219 ± 0.002	73.14 ± 0.12	0.17
0.7933 ± 0.0005	47.598 ± 0.030	0.20
0.6606 ± 0.0004	39.637 ± 0.021	0.20

along with the expected attenuation for a sinusoidal modulation. The mean flux was $\sim 2.5 \times 10^{-8}$ erg cm⁻² s⁻¹, at least two to three times greater than that seen from 3U1727–33 by Uhuru⁶.

The Ariel V experiment C detector⁷ observed the same region of sky for 3 d beginning on March 8, 1976, and again for one day on March 24, 1976 (ref. 8). The experiment C field of view is circular with a f.w.h.m. of 5° , and contained within it were all the sources observed by Copernicus, plus MX1716–30 (ref. 9).

Data with 0.5, 20 and 32 s resolution were obtained in the 2–7 keV range⁸. Both observations have been subjected to a power spectrum analysis and no significant periodicities were detected in the range 45 min to 40 s, with an upper limit of 4% of the mean flux. We then repeated the analysis for each individual orbit of data. In only one orbit (7784, with a time resolution of 20 s) was a significant periodicity detected; this period was 73.1 ± 1.4 s with a probability of random occurrence of 10^{-13} . We note that this period is close to one of the possible aliased periods in the 1973 Copernicus data (Table 1). The mean amplitude of the modulation during this orbit was $14 \pm 3\%$ of the mean flux. Figure 2 illustrates the data of both this orbit and one

Table 2 Power law fit: $I(E) = CE^{-\alpha} \exp(-\sigma N_H)$

Ariel V experiment C (2.1–20.3 keV)			
Start time day, March 1976	C	α	$N_H \times 10^{22}$
8.570	2.35 ± 0.20	2.05 ± 0.07	5.34 ± 0.02

16.3	3.5 ± 1.8	2.7 ± 0.5	12 ± 6

preceding it. For the orbit where a modulation was detected the predicted times of maximum flux are indicated. Upper limits on a 73-s modulation obtained for the other 20 s and also the 0.5-s orbits were typically a factor of 3 less than the amplitude of the modulation detected. The mean count rate of each orbit (a flux of $\sim 2.2 \times 10^{-9}$ erg cm⁻² s⁻¹) did not vary by more than ~8%, in particular there was no significant difference between the mean count of the orbit 7784 and those close to it.

Spectral data were obtained on several occasions throughout the first Ariel observation with a time resolution of ~40 min and the results are presented in Table 2. These represent the background subtracted average of all the

Fig. 1 The count rate and flux seen in the April 14–15, 1973 Copernicus observation. The mean intensity recorded by Copernicus in May 1976 is indicated.

sources in the field of view. There is no evidence for any significant spectral variability.

A further half day observation of this region was made by Copernicus on May 16, 1976. The mean count rate observed was ~ 30 counts min^{-1} ($\sim 1.3 \times 10^{-9}$ erg cm^{-2} s^{-1}). The data as a whole show no significant modulation in the

least 50 pulses. As for the first case, there is the possibility that a repetition of the 73-s period has occurred after 3 yr. If this is so, then the modes of oscillation must be limited in number, otherwise the probability of the reappearance of a periodicity would be negligible.

We thank C. Chevalier and S. A. Ilovaisky for discussions,

Fig. 2 The background subtracted count rate and flux observed by Ariel V experiment C during two successive orbits 7782 and 7784, in March 1976. For ease of comparison the flux axes have been set to the same as Fig. 1. Also shown are all the data from orbit 7784 folded about a period of 73.14 s and repeated once for clarity.

period 40 min–40 s with an upper limit of 12% of the mean flux. If, however, a transient periodicity such as that seen by Ariel V had been present it would not have been detected because of the poorer statistical significance of the data. Spectral information was obtained with a 6-channel PHA and the spectral parameters obtained are shown in Table 2.

There are two possible interpretations of the data:

(1) The 1973 Copernicus periodicity originated from a regularly pulsating source similar to those reported in ref. 6. Since a similar modulation was not re-observed in 1976 this suggests that either the periodicity originated from a transient source similar to that seen by Ives *et al.*¹⁰, or else the amplitude of the modulation is variable. In the latter case the 73-s periodicity seen in March 1976 could be the fundamental period of the pulsator, or its apparent relationship to the 7.9 min period is coincidental.

(2) The modulation seen in 1973 resulted from a periodic sequence of bursts originating from a burst source in the field of view. The period between bursts would be either 7.9 min or any of its aliases (Table 1). We note that such sequences of bursts have been seen from several burst sources on various time scales (refs 4, 11). In particular MXB1730–335 shows quasi-periodic bursts trains with characteristic time scales between 15 and 35 s (refs 5, 8). To explain the 1973 data we require that bursts trains can be stable for at

Mrs P. Ock for assistance with computing and Professor R. L. F. Boyd, for encouragement. The financial support of both the SRC (N.E.W. and K.O.M.) and ESA (G.B.) is acknowledged.

Spiral structure as an explanation for the asymmetric brightness of Saturn's A ring

REITSEMA *et al.*¹ and Lumme and Irvine² have recently confirmed earlier observations which suggested that the A ring of Saturn is fainter in the quadrants following conjunctions of the particles with the Earth-Saturn line and brighter in the quadrants preceding conjunctions. Surprisingly, no intrinsic azimuthal brightness variation is found in the B ring. The brightness variation has been linked to the presence of synchronously rotating particles in the A ring, the effect caused by either a systematic variation in albedo over their surfaces or variations in their geometric projections. Of these two possibilities, the latter seems more promising since the asymmetry of the brightness variation with respect to the Earth-Saturn line is difficult to account for by means of an albedo variation. Furthermore, an albedo variation would yield the same brightness pattern for the B ring if it contained synchronously rotating particles. In this paper, however, we propose yet another mechanism to explain the phenomenon—spiral wakes in the A ring.

The asymmetry would arise in a ring of synchronously rotating, irregularly shaped, particles if there was a statistical tendency for the long axes of the particles to be inclined in the trailing sense with respect to the differential rotation. Such an orientation of the axes of the particles could arise naturally as the result of interparticle collisions and the shear from differential rotation. What is required is that the collision frequency be comparable to the libration frequency of the long axes of the particles (which is $\sim \Omega$, the orbital frequency, for irregularly shaped particles), and that the orbits of the particles deviate from circles by no more than a few times the particle radii a . The first requirement is probably met in Saturn's A and B rings, since their normal optical depths τ_1 are ~ 1 . It is the second requirement that seems unlikely to be satisfied and to which we now turn our attention.

The brightness surge of Saturn's rings as opposition is approached is most plausibly interpreted as the consequence of shadowing in rings that are many-particle radii thick. Best current estimates for the volume density give $D \sim 10^{-3}$ (ref. 3). D is simply related to the vertical thickness of the rings by $D \sim a\tau_1/h$. The random velocity of the particles $v \sim \Omega h$. These relationships imply $v \sim a\Omega\tau_1/D \sim 10^3 a\Omega$ for $D \sim 10^{-3}$ and $\tau_1 \sim 1$. Collisions will produce approximate equipartition between random and rotational kinetic energies, and thus we conclude that the particles in Saturn's rings should have spin periods that are $\sim 10^{-3}$ times their orbital periods. Of course, this conclusion applies in an average sense to the particles that scatter the sunlight. The angular spin velocities ω of individual particles should vary as $(\omega - \Omega) \propto a^{-3/2}$. Thus, particles whose radii are larger than average (the average radius \bar{a} clearly being determined by weighting with respect to surface area) by a factor equal to or greater than

$$\frac{a_1}{\bar{a}} \sim 2^{1/5} \left[\frac{\tau_1}{D} \right]^{2/5}$$

would have $|\omega - \Omega|/\Omega < 1$. A significant fraction of such large particles would be at least temporarily trapped in synchronous rotation if they were irregular in shape. The azimuthal brightness variation might be accounted for if large particles, $a > a_1$, scattered a significant fraction ($\gtrsim 10\%$) of the sunlight incident on the A ring. There is, however, a more attractive mechanism which we shall now describe that is capable of producing the observed effect.

Large particles, whose surface escape velocities are $> v$, will force intense trailing density wakes. Such wakes have been studied previously in connection with spiral structure in galaxies⁴. The detailed mechanics of the formation of wakes in a ring composed of inelastically colliding particles is certain to

be complicated. On the basis of the study cited above, however, there is no doubt that in differentially rotating media these wakes are always oriented in the trailing sense! The dimensions of the trailing density concentrations will range up to a few times the ring thickness h . Since $h \lesssim 4$ km (ref. 3), these density wakes are much too small to be resolved from the Earth but might be resolved by the Mariner Jupiter/Saturn spacecraft due to fly by the planet in 1980. The density wakes, if optically thick, will scatter sunlight in a manner that mimics scattering by synchronously rotating, irregular particles whose long axes are inclined in a trailing sense. The particles in a wake would, however, be only transient neighbours and in no way would a particle and its wake constitute a rigidly rotating entity.

Particles whose surface escape velocities are $\sim v$ have radii $a_2 \sim v/(8G\rho)^{1/2}$. Using the relationships developed previously, we find

$$\frac{a_2}{\bar{a}} \sim \frac{\Omega}{2(2G\rho)^{1/2}} \left(\frac{\tau_1}{D} \right)$$

This expression is to be compared with the expression for a_1/\bar{a} derived earlier. It is easily shown that

$$\frac{a_2}{a_1} \sim 2^{-7/10} \frac{\rho_s}{\rho} \left(\frac{R_s}{r} \right)^3 \left(\frac{\tau_1}{D} \right)^{3/5}$$

where $\rho_s = 0.7$ g cm⁻³ and $R_s = 6 \times 10^9$ cm are the mean density and the mean radius of Saturn. Taking $\rho = 1$ g cm⁻³, $r = 1.3 \times 10^{10}$ cm, $\tau_1 = 0.5$ and $D = 10^{-3}$, which are appropriate parameters for ice particles near the centre of the A ring, we obtain $a_2/a_1 \sim 0.4$. Thus, particles that are large enough to rotate synchronously will also force dense trailing wakes.

To this point, our discussion has been based on the assumption that the opposition effect implies $D \sim 10^{-3}$. We stress that if this assumption were incorrect and $D \gg 10^{-3}$, our conclusion, that density fluctuations rather than synchronously rotating particles are responsible for the azimuthal brightness variation, would be strengthened (note $a_2/a_1 \propto D^{-3/5}$). Furthermore, if the mean mass density in the rings were as high as 0.1 g cm⁻³, the rings would be on the brink of gravitational instability^{5,6}. In this case, collective gravitational effects would greatly enhance the strength of trailing density perturbations⁴.

The absence of an azimuthal brightness variation in the B ring must still be explained. Two possibilities immediately come to mind. First, the higher optical depth of the B ring would make its brightness less sensitive to either the geometrical orientations or the spatial correlations of the individual particles. Second, both mechanisms for producing the azimuthal brightness variation require the rings to contain particles whose radii are considerably larger than average. Small particles are more likely to gravitationally aggregate and form large particles in the A ring than in the B ring. In this context, we note that the formal Roche limit for particles with $\rho = 1$ g cm⁻³ occurs at $r = 1.3 \times 10^{10}$ cm, near the centre of the A ring.

Circumstellar acetylene in the infrared spectrum of IRC +10° 216

A THICK, expanding envelope of dust and gas surrounds the unusual object IRC +10° 216. Microwave studies have identified numerous molecular constituents of the envelope¹, and the thermal infrared spectrum indicates the probable presence of both silicon carbide and graphite in the form of dust grains (ref. 2, and M. P. Campbell, *et al.*, unpublished). We report here the detection of acetylene, C₂H₂, in the infrared spectrum. Although acetylene is expected to be an important constituent of some stellar atmospheres, and possibly of interstellar molecular clouds, this appears to represent the first positive detection of C₂H₂ outside the solar system.

A Fourier transform spectrometer at the coudé focus of

the Mayall 4-m telescope at Kitt Peak was used to obtain a spectrum of the region 4,000–5,000 cm⁻¹ (2.0–2.5 μm). This was a daytime observation, and a solar reference spectrum was recorded with a small heliostat shortly before and at similar zenith distance. A very small portion of these spectra are shown in Fig. 1. The +10° 216 spectrum contains a resolved, red degraded feature at 4,091 cm⁻¹ which we attribute to the ν₁+ν₅ band of acetylene³. Only the Q branch is detectable. Lines Q(1) to Q(7) fall in an interval of only 0.12 cm⁻¹. In the P and R branches, the lines are too widely separated to yield distinctive features.

The strength of the feature drops sharply near J=16, suggesting a temperature of 200–300 K, so the absorption is most probably associated with the 2'' diameter circumstellar shell⁴. Adopting a temperature of 250 K, the strongest acetylene absorption would be expected to occur at 4,090.98 cm⁻¹. The observed maximum absorption, corrected for the Doppler shift appropriate for the 2'' shell (ref. 5 and D. N. B. Hall, *et al.*, unpublished), falls at 4,090.97 ± 0.03 cm⁻¹, indicating the internal consistency of our interpretation. From published spectra^{6,7} and intensity studies^{8,9} we estimate a ν₁+ν₅ Q branch intensity of 0.2 cm⁻² atm⁻¹. The observed equivalent width of 0.2 cm⁻¹ then requires a column abundance ~1 cm atm, or 3 × 10¹⁹ mol cm⁻². For a 2'' diameter shell and a distance of 200 pc (D. N. B. Hall, *et al.*, unpublished) this corresponds to a total mass of ~10⁻⁴ M_⊙.

Of the other important C₂H₂ bands only the 3.04-μm band⁹ should definitely be detectable in existing +10° 216 spectra. A previously unidentified band in fact occurs in many carbon stars¹⁰ at the correct position. The strength of this band in +10° 216 (~90 cm⁻¹) could reasonably arise from 1 cm atm of acetylene, and we suggest that acetylene does in fact contribute part or all of this feature. Absorption in the 3 μm region from other hydrocarbons is, however, likely in carbon-star photospheres, and cannot be ruled out in the +10° 216 shell.

Except for the 2–0 band of CO (D. N. B. Hall, *et al.*, unpublished) no other lines were found in the 4,000–5,000 cm⁻¹ region to a limiting equivalent width of ~0.05 cm⁻¹. From laboratory spectra¹¹ of the 2.32 and 2.37 μm bands of methane, we estimate a CH₄ abundance <0.03 cm atm, or 7 × 10¹⁷ mol cm⁻².

IRC +10° 216 is apparently a site of continuing production and ejection of grains and molecules. In view of the serious difficulties encountered in developing a satisfactory understanding of these processes, +10° 216 deserves detailed and continuing study. In particular, two important questions may be resolved by continued investigation: first, is grain formation a cause or an effect of mass ejection?; second, do molecular abundances 'freeze out' on ejection? Our results for C₂H₂ and CH₄ (which are not detectable in the microwave region because of lack of pure rotational dipole transitions) are particularly relevant to the second question. The large C₂H₂ abundance, comparable to the CO abundance (ref. 5 and D. N. B. Hall, *et al.*, unpublished), is consistent with computations for cool, carbon rich stellar photospheres¹². The predominance of C₂H₂ over CH₄ is also expected. If the photosphere were ejected in such conditions that it cooled while maintaining molecular equilibrium, however, C₂H₂ should be strongly depleted¹³. Morris¹ has compared relative abundances of SiS, SiO, CS and HC₃N with recent molecular equilibrium calculations¹⁴. While inconclusive, his results did not rule out 'freezing' of photospheric abundances. Additional spectroscopic study should provide crucial relative abundances (or upper limits) for C₂, CN, HCN, and possibly others, permitting a more conclusive analysis of the evolution of the molecular abundances during ejection.

A number of infrared objects are known which appear to be similar to +10° 216 (ref. 10). In addition, certain bright carbon stars show a 10-μm flux excess, attributed to circum-

Fig. 1 The spectrum of IRC +10° 216. Above, a comparison solar spectrum (dominated by terrestrial absorption); middle, the sum of two +10° 216 spectra; below, the ratio +10° 216/sun. A 2σ error bar, computed from the difference of the two +10° 216 spectra, is shown at the lower right. The resolution is 0.25 cm⁻¹, and the FWHM of the instrumental line profile is 0.30 cm⁻¹. The abscissa scale at the bottom is in units of 1 cm⁻¹/tic (vacuum) increasing to the right; at the top, units are 10 Å/tic (STP) increasing to the left. The Doppler shift of +10° 216 at the time of observation was negligible for purposes of this figure, but has been accounted for in the analysis. In the ratio +10° 216/sun the small peak at 4,090.52 cm⁻¹ is an artefact arising from a weak absorption line in the solar spectrum.

stellar dust¹⁸. We have obtained a spectrum of one of the latter, V Cygni. In this star the 4,091 cm⁻¹ band appears prominently, stronger than in +10° 216, and apparently originating in a circumstellar region of somewhat higher temperature. It is possible that the circumstellar acetylene and dust grains are mixed at a common kinetic temperature. If so, progress may be possible in the difficult problems of determining grain emissivity and particle size distribution.

Time-varying Newtonian gravity and universal motion

A TIME-dependent gravitational constant $G(t)$ was proposed by Dirac¹ in 1937, and there is some limited evidence for it^{2–4}. It can be incorporated in relativistic theories of gravitation (see refs 5–7), but the resulting equations are liable to be cumbersome, and it is uncertain which theory should be used. Attempts to consider this problem in a Newtonian framework^{3,4,8–10} have been based on the amended Newtonian force law

$$\mathbf{F} = -G(t) \frac{m_1 m_2 \mathbf{r}}{r^3} \quad (1)$$

We show here that the assumption of energy conservation (as discussed below) leads to a more substantial change in the force law.

That equation (1) implies violation of energy conservation for particle interactions can be seen as follows. One particle, shaped like a doughnut, moves from infinity directly towards a second particle; the particles move through each other to infinity. If $G(t)$ is decreasing, then, for the same distance of separation, the force of attraction whilst the particles are approaching is greater than the force whilst the particles are moving apart. The final relative velocity for large separation is greater than the initial relative velocity. Thus the final kinetic energy is greater than the initial kinetic energy. Since the potential energy is zero for large separation, energy conservation for interacting particles has been violated; the energy of the gravitational field is

not involved. Energy conservation for interacting static bodies would of course also be violated.

We see that energy conservation and equation (1) cannot both hold in the generalised Newtonian theory. In the past the failure of the energy law appears to have been ignored, and equation (1) has been maintained, presumably as the more physically important of the two laws. In this note an alternative path is explored: a new force law will be obtained from energy conservation, which, together with expressions for kinetic and potential energy, will be assumed.

We consider a finite set of discrete particles with masses m_α ($\alpha = 1, \dots, N$). We shall take the potential energy, V , of the system in the general form

$$V = \frac{1}{2} \sum_{\substack{\alpha, \beta=1 \\ \alpha \neq \beta}}^N m_\alpha m_\beta v(r_{\alpha\beta}, t) \quad (2)$$

Referring to a chosen inertial frame, \mathbf{x}_α is the position vector of the particle α ; $\mathbf{r}_{\alpha\beta} = \mathbf{x}_\alpha - \mathbf{x}_\beta$; $r_{\alpha\beta} = |\mathbf{r}_{\alpha\beta}|$; and the function

$$v(r_{\alpha\beta}, t) = \frac{-G(t)}{r_{\alpha\beta}} \quad (3)$$

would be the obvious choice. The kinetic energy of the system has the usual form, and the energy conservation law is

$$\sum_{\alpha=1}^N \frac{1}{2} m_\alpha \sum_{l=1}^3 \dot{x}_{\alpha l}^2 + \frac{1}{2} \sum_{\substack{\alpha, \beta=1 \\ \alpha \neq \beta}}^N m_\alpha m_\beta v(r_{\alpha\beta}, t) = E \quad (4)$$

where E is a constant. Total differentiation with respect to time of equation (4) leads, after some algebra, to

$$0 = \sum_{\alpha=1}^N m_\alpha \sum_{l=1}^3 x_{\alpha l} \left(\dot{x}_{\alpha l} + \sum_{\substack{\beta=1 \\ \beta \neq \alpha}}^N m_\beta \left[\frac{\partial v}{\partial r_{\alpha\beta l}} + \frac{\dot{r}_{\alpha\beta l}}{V_{\alpha\beta}} \frac{\partial v}{\partial t} \right] \right) \quad (5)$$

where $V_{\alpha\beta} = |\dot{\mathbf{r}}_{\alpha\beta}|$. Equation (5) suggests, and is consistent with, the force law ($i = 1, 2, 3$)

$$x_{\alpha i} = - \sum_{\substack{\beta=1 \\ \beta \neq \alpha}}^N m_\beta \left[\frac{\partial v}{\partial r_{\alpha\beta i}} + \frac{\dot{r}_{\alpha\beta i}}{V_{\alpha\beta}} \frac{\partial v}{\partial t} \right] \quad (6)$$

A formal approach to the preceding paragraph is as follows. Newton's three laws of motion apply, and the particle interaction force is assumed to be given by equation (6). Equation (5) follows immediately, and may be integrated to show that equation (4) is a constant of the motion. Because of the form of equation (4), it is physically appealing to identify this constant as the energy.

The ratio, X , of the second term to the first term in equation (6), subject to equation (3), is estimated for a particle moving with speed V (cm s⁻¹) on the surface of the Earth (taken as a sphere of radius r)

$$|X| \simeq \left| \frac{\dot{G}}{G} \right| \frac{r}{V} < \frac{10^{-8}}{V}$$

where $|\dot{G}/G| < 10^{-10} \text{ yr}^{-1}$ has been used. For two atoms at a distance apart, a , $\sim 10^{-8} \text{ cm}$ in a solid at absolute temperature T , taking $V \simeq (kT/m)^{1/2}$, one finds similarly

$$|X| \approx \left(\frac{m}{kT} \right)^{1/2} a \left| \frac{\dot{G}}{G} \right| < \frac{10^{-20}}{T^{1/2}}$$

The correction to the second term in equation (6) is thus normally negligible.

Even if equation (3) is not used, the force law, equation (6), has the remarkable implication that if the law of gravitation, equation (2), is time-dependent, then, to avoid infinite forces, no two particles in the Universe may be at relative rest for a non-zero time interval. The subject of statics must be considered as an approximation if the above ideas are accepted, quite apart from arguments based on quantum mechanics. Our principle of universal motion is in agreement with the observed fact that physical systems on all scales are in states of relative motion: there are zero point vibrations in condensed systems; planets orbit stars; galaxies rotate; and the Universe itself is expanding.

In conclusion, we note the following points:

(1) Newtonian cosmology with time-varying gravity has been discussed previously using an energy conservation law^{11,12}. The application of the force law, equation (6), to cosmology has been considered¹³, and yields results consistent with the energy approach.

(2) Equation (6) is Machian, in that the force on a particle depends on the velocity of all other particles in the Universe.

(3) Since equation (6) leads to an interparticle force which need not act along the line joining the two particles, angular momentum is not conserved in general.

(4) It would be desirable to find a variational principle leading to equation (6).

One of us (N.T.B.) is indebted to the SRC for support.

Thermal alteration of young kerogen in relation to petroleum genesis

AVAILABLE evidence indicates that petroleum hydrocarbons can be generated by alteration of kerogens through geothermal heating¹⁻³. In this study we have separated kerogen, humic acid and lipid (benzene-methanol extractable) material from a young marine sediment (Tanner Basin, offshore California) and heated it in sealed glass tubes in a nitrogen atmosphere. Each tube was heated at a single temperature between 150 and 410 °C for a specified time in the range 5–120 h. Gaseous and liquid (benzene-methanol extractable) products generated during the heating, as well as the residual organic material, were characterised by gas-liquid chromatography, elemental analysis, infrared and electron

Fig. 1 Changes in H/C ratio and percentage C of kerogen when heated.

spin resonance (ESR) spectroscopies, and X-ray diffraction.

The sediment sample used has approximately 6% (by dry weight) of organic carbon. The lipid, humic acid and kerogen fractions account for 10, 7 and 72% of the total organic matter, respectively. Unheated kerogen contains 56.7% carbon, 6.5% hydrogen, 6.0% nitrogen and 30.8%

Fig. 2 Relationship between ESR properties of kerogen and its H/C ratio.

Fig. 3 Total normal alkanes and liquid product generated are plotted against the H/C ratio of kerogen.

oxygen (by difference) on an ash-free basis, and seems to fit into the type III kerogen classification of Tissot *et al.*³.

With increasing time and temperature, between 150 and 410 °C, the carbon content of kerogen increased from 56.7 to 82.1% and its atomic H/C ratio decreased from 1.37 to 0.49 (Fig. 1). Therefore, the values of either percentage C or the H/C ratio of residual kerogen may be used as an index for "level of organic maturation" (LOM) for this type of kerogen. Figure 2 shows plots of H/C ratios of residual kerogen against various parameters derived from ESR spectroscopy. With increasing degree of thermal alteration of kerogen, spin concentration increases, which may be closely associated with bond cleavage and hence, the elimination of functional groups. Below an H/C value of 0.7, the spin concentration decreases again, due to the gradual conversion of kerogen to a graphite-like structure, as verified by X-ray diffraction analysis. The kerogen g-value decreases with increasing degree of thermal alteration. This indicates the change of free radicals from semi-quinone type to radicals of carbon, nitrogen and sulphur due to imperfection in the kerogen structure⁴. Changes in ESR

characteristics on heating follow the same general pattern as those described by Pusey⁴ for kerogen in sedimentary rocks and Van Krevelen⁵ for coals (Fig. 2).

During heating, kerogen produced large amounts of gaseous product, amounting to about 40% of the initial weight at 410 °C. In the initial stages of thermal alteration, only H₂O and CO₂ were evolved. With increasing degree of thermal alteration, hydrogen, methane and other volatile hydrocarbons began to be generated, and their content increased gradually.

In addition, liquid products soluble in organic solvents began to be produced at a low temperature of alteration, reached a maximum at a kerogen H/C ratio of 0.90–0.95, and then decreased as thermal alteration increased. The decrease in the amount of liquid product may be explained by its further decomposition on heating. In Fig. 3a, the relationship between the total (C₁₃–C₄₁) normal alkanes or paraffins generated and H/C of kerogen is recorded. For the Tanner Basin kerogen, paraffins begin to be generated around H/C=1.1, increase sharply, reach a maximum

Fig. 4 Generation mechanism of n-alkanes from kerogen on heating.

around H/C=0.8, and then decrease rapidly. The apparent activation energy of the generation of the total n-alkanes was calculated to be 31 kcalorie mol⁻¹, which is lower than that of the breakage of C–C bonds in n-alkanes (58 kcalorie mol⁻¹)⁷. Therefore, generation of n-alkanes from kerogen may be due to the breakage of bonds other than C–C, for example, functional side chains on aromatic or cyclic rings, or compounds containing O, N or S, where the activation energy for bond breakage is lower than for paraffins⁸.

It is quite interesting to note that the H/C ratio of Tanner Basin kerogen at the maximum production of total liquid product (H/C=0.90–0.95; see Fig. 3b) is different from that at the maximum production of n-alkanes (H/C=0.8). This suggests that paraffins may be generated by the subsequent decomposition of the liquid product. A similar conclusion was reached by Tissot's group in the heating experiment of kerogen from a shale⁹. To elucidate further the mechanism of hydrocarbon generation, our kerogen was heated at 260 °C for 18.5 h, the optimum conditions for the generation of liquid product but too low to produce much n-alkanes. By this reaction, liquid product (LP_A) and kerogen (A) were obtained, and then those two fractions were heated again at higher temperature (330 °C, 24 h) to produce paraffins (Fig. 4). Clearly, the liquid product obtained on heating at the lower temperature is more aliphatic (H/C=1.37) than the residual kerogen (A) (H/C=1.07). By the second heating at the higher temperature, the liquid product (LP_A) produced a large amount of normal paraffins, as well as highly aromatic kerogen-like material. Heating the kerogen (A), also pro-

Fig. 5 Changes in the amount of total *n*-alkanes generated from various organic fractions on heating at various temperatures for 24 h.

duced alkanes and highly aromatic kerogen (B), but only about a third of the amount produced from the liquid product (LP_A). These results support the model for the production of normal hydrocarbons proposed by Tissot's group.

Interestingly, the distribution pattern of *n*-alkanes generated from kerogen during the initial stage of thermal alteration, showed an even carbon number predominance (CPI ≈ 0.5). With increasing degree of thermal alteration, the distribution pattern approached that of petroleum hydrocarbons (≈ 1.0).

The results of heating other organic sediment fractions (lipid and humic acid) showed that these fractions also have an ability to produce paraffinic hydrocarbons (Fig. 5). The amounts produced are, however, very different. The contribution of each organic fraction to the total alteration was calculated for the Tanner Basin sediment sample. The lipid fraction accounts for 58%, humic acid 0.4% and kerogen 41% of the total amount of normal hydrocarbons produced.

Photocell using covalently-bound dyes on semiconductor surfaces

We have developed a new type of electrochemical photocell, using an optically transparent semiconductor electrode whose surface was modified by the chemical binding of sensitising dyes. In spite of the absence of dye in the solution, a photocurrent, as large as those previously observed at the unmodified electrodes in contact with the dye solutions was obtained.

Since the initial report by Fujishima and Honda¹ on a photocell employing a TiO₂ n-type semiconductor as the photoanode to decompose water under illumination by photons of energy greater than the band gap, there has been much research²⁻⁶ on this subject because of its important implications for solar energy conversion and hydrogen production. Photosynthetic light conversion⁷⁻¹⁰ in green plants has also been studied. From the commercial use of electrochemical photocells as solar energy conversion devices, the photoelectrodes should be stable on illumination in aqueous solutions. TiO₂ and SnO₂ are the two candidates that have been so far found to be inert¹¹⁻¹³. The band gaps of TiO₂ and SnO₂ are, however 3.0 eV (ref. 14) and 3.5 eV (ref. 15) respectively which correspond to photon wavelengths of 415 and 355 nm. Solar energy reaching the Earth's surface has a spectrum distribution in longer wavelength¹², and cannot therefore be used. Effective ways of extending the sensitivity of electrochemical photocells to longer wavelengths are therefore strongly desired. A better way to solve the problem would be spectral sensitisation, in analogy with the primary light reaction of photosynthesis, where chlorophyll molecules accept the solar energy. A noticeable anodic current can be seen in electrochemical cells containing an n-type semiconductor anode in contact with certain dye solutions when illuminated with light in the spectral region where the dye absorbs, even though of energy less than the band gap of the semiconductor. This electrochemical spectral sensitisation works for various electrode materials, including TiO₂ (ref. 16) and SnO₂ (ref. 17), and has been mainly studied to elucidate the mechanism of the spectral sensitisation, since Gerischer *et al.*¹⁸ started using ZnO single crystal.

As sensitisers, dyes belonging to the xanthene and the cyanine groups have been widely used. Gerischer and Tributsch¹⁸ observed also an increase in the sensitised photocurrent on adding of reducing agent, such as hydroquinone,

Fig. 1 An electrochemical photocell consisting of an optically transparent semiconductor anode chemically modified with rhodamine B (1) and a Pt cathode (2) in contact with an electrolyte containing a redox system (3). As a light source, a 500-W xenon lamp (5) was used in conjunction with filters and/or a monochromator (4). For measurements of spectral sensitisation (shown in Fig. 2) the electrode was polarised with a conventional potentiostat using a saturated calomel electrode (6) with a Luggin capillary.

Na_2SO_3 , or H_2O_2 , to the dye solution, although the reducing agents show no absorption in the visible region. This phenomenon is termed 'supersensitisation.'

For a real photocell, however, a new problem may arise: most of the solar energy is absorbed ineffectively by the dye molecules in the solution rather than by the adsorbed dye molecules at the electrode-solution interface, though only the excited adsorbed dye molecules can contribute to sensitisation²⁰.

To cope with this, a new type photocell has been developed (Fig. 1). The chemically modified SnO_2 or TiO_2 electrode with rhodamine B as a sensitizer is in contact with the transparent electrolyte solution containing a reducing agent as a supersensitizer. The procedure to modify the electrodes was similar to that previously described²¹, but synthesis of amide-linked rhodamine B by the dehydrative coupling of a carboxyl group of rhodamine B with propylamine modified electrodes was carried out using dicyclohexylcarbodiimide (DCC) as a dehydrating agent because it gives a better yield than the two-step reactions, involving the preparation of acid chloride of rhodamine B using thionyl chloride and the acylation of the propylamine

M = Sn or Ti. HOOC-RhB = rhodamine B

modified electrodes with the acid chloride. The propylamine modified TiO_2 electrodes were prepared in the same manner as the propylamine modified SnO_2 electrodes²¹ by the method developed by Murray *et al.*²². The surface reactions and confirmatory chemical tests were followed by X-ray photoelectron spectroscopy²³.

Since the rhodamine B was covalently bound by silyl ether and amide bonds to the electrode surface, the dye remained almost permanently on the electrode surface, unless the pH value of the electrolyte solution was extremely low or high. Unwanted decomposition of the dye in the course of

Fig. 2 Spectral dependence of the photocurrent for optically transparent SnO_2 electrodes polarised anodically at + 0.35 V against SCE, and illuminated through the electrode (Fig. 1). *a*, Photocurrent spectrum sensitised by a sub-monolayer of rhodamine B covalently bound to the electrode surface through amide bonding at the chemically modified SnO_2 electrode in contact with a transparent electrolyte (0.2 M Na_2SO_4) containing hydroquinone (5×10^{-3} M) as a supersensitizer. *b*, Photocurrent spectrum at the conventional unmodified SnO_2 electrode in contact with a rhodamine B solution (5×10^{-4} M rhodamine B + 5×10^{-3} M hydroquinone in 0.2 M Na_2SO_4).

the sensitisation process was almost entirely suppressed by the presence of the supersensitizer in the solution²⁴.

A typical sensitised photocurrent spectrum obtained with the modified electrode is shown in Fig. 2, as well as a spectrum obtained with the conventional untreated electrode in contact with rhodamine B solution containing the same amount of supersensitizer. The anodic photocurrents observed at the modified electrode, whose spectral dependence was quite close to that of the dye's absorption spectrum, is the same order of magnitude as those observed at the unmodified electrode, even though there is no dye in the solution. Since a monolayer coverage of the dye absorbs very little light^{24,25}, the modified electrodes are almost indistinguishable to the eye from the unmodified ones, and SnO_2 electrodes are transparent in the visible region. Accordingly, further improvements in efficiency can be easily attained by immersing many modified electrodes in the electrolyte solution in parallel containing colourless supersensitizers, and then by illuminating them perpendicularly.

Perhaps, the illumination of the electrode-electrolyte interface in a multiple internal reflection mode, (ATR, refs 24-27) will also be effective, since the chemically bound dyes on the surface can be excited by the 'evanescent wave', and loss of energy through reflections can be avoided in this mode. Extension of the useful spectral region may be possible by binding various sensitizers.

Cultural, language and geographical correlates of genetic variability in Andean highland Indians

The genetic structure of primitive human populations has been studied for the purposes of understanding hominid evolution and developing more cogent genetic models. For this it is important not only to demonstrate genetic variability between populations, but also to explore the correlates of such variability. Using data on several Chilean Indian populations I have found that genetic differentiation can best be ascribed to geographical separations. Other correlates, such as culture and language, are of secondary importance when the relationship is studied simultaneously by a stepwise regression technique¹. Although I consider here a particular set of populations, the results obtained

Table 1 Correlation coefficients between genetic, geographical, cultural and linguistic variations among seven Chilean Indian tribes and their association with each tribe's extent of Indian ancestry

	Geographical distance	Cultural dissimilarity index	Linguistic dissimilarity index	Probability of Indian ancestry
Genetic	0.716*	0.775*	0.032	-0.018
Geographical	—	0.901*	0.323	-0.142
Cultural	—	—	0.147	0.016
Linguistic	—	—	—	-0.194

*Significant at 0.01 level.

seem to be fairly generally applicable². I have found an empirical relationship between geographical distance and gene identity for the Andean highland Indians discussed here.

There have already been attempts to relate genetic differentiation within a tribe or between several primitive tribes to linguistic, social, topographical and environmental components of the population²⁻⁸, but the conclusions were not always unequivocal. This is partly because all such correlates are themselves associated with one another, so that a simple analysis of variance as advocated by some researchers⁷, or a simple pairwise correlation⁴ may result in an unwarranted interpretation of the results.

The Chilean Indian tribes considered in this analysis are

organisation of the seven tribes. Another correlate was the linguistic variability which emerged from the nested hierarchical classification of Andean languages¹⁴. From the approximate geographical location of the tribes, the geographical distance between them was computed following standard physical transformation. As all the tribes have intermixed with Caucasoid invaders, the variation in the degree of Caucasoid admixture as determined from the ABO blood group were used to derive the probability of Indian ancestry for any two genes of the tribes.

To determine the nature of interrelations among these measures of variability, I first present the correlation coefficients between them using all the pairwise tribe-comparisons ($C_2=21$, see Table 1). Cultural and

Table 2 Results of a stepwise regression analysis identifying interrelationships between the different variability measures in Chilean Indian tribes

Variables entered	% Variance of genetic distance explained Cumulative	Marginal	F ratio (for each successive step)	Probability
Geography	51.31	51.31	20.02	$P < 0.001$
Culture	60.19	8.88	4.01	$0.05 < P < 0.1$
Language	61.48	1.29	0.57	$0.4 < P < 0.5$
Probability of Indian ancestry	61.52	0.04	0.02	$0.8 < P < 0.9$

the Aymara (17°S, 70°W), Atacameño (23°S, 67°W), Diaguita (22°30'S, 63°42'W), Pehuenche (38°S, 71°30'W), Mapuche (38°S, 72°30'W), Acahuaf (50°S, 75°W) and Yagan (55°36'S, 70°48'W), all so-called 'highland' Andean tribes. Gene frequencies for seven serological markers (ABO, MNSS, Rh, Diego, Duffy, Kell and haptoglobin) common to each population were extracted from the literature⁴⁻¹². To measure the genetic differentiation based on these markers, I computed the standard genetic distances between the different tribal groups, using the methods of Nei¹³.

As a first correlate of genetic differentiation, I constructed a cultural dissimilarity matrix taken directly from work⁴ involving an extensive literature survey of Andean culture. The basic features involved in cultural classification were the mode of subsistence, economics and social

geographical distances are almost linearly related ($r=0.901$). Linguistic dissimilarity was a poor correlate of genetic differentiation ($r=0.0320$, $P>0.85$). When geographical distance is used as the only regressor to explain genetic variabilities in the seven tribes, about 51.3% of the total variance is explained. All the other variables (cultural and linguistic variabilities, and variation in rates of admixture with Caucasians) explain only a marginal amount (10.2%). The result of such a regression analysis is shown in Table 2. This analysis also indicates that of all the variables, only geographical distance seems to be important, explaining the trend in genetic variabilities in these seven Andean populations. This agrees with theoretical predictions¹⁵. The relationship between genetic distance and geographical distance can be studied further by relating the probability of allelism between two homologous genes with the geographical distance by which two groups are separated. The probability of allelism, or the probability of gene identity between two populations, I_r , is given by $I_r = \exp(-D)$, where D is Nei's measure of standard genetic distance¹³. Figure 1 represents the empirical relationship between normalised gene identities (I_r) and geographical distances (r) for the 21 tribe comparisons. The least square fit of $I_r = 0.973 + 0.027 \exp(-r/1,000)$ is statistically satisfactory ($0.05 < P < 0.1$), although there are a few large deviations from expectations towards the tail of the curve.

There is also a high association between cultural and genetic variabilities in the seven tribes (Table 1), but this may be an artefact of the other two significant values in the same table. Such an association is also exhibited through the regression analysis, in the sense that in addition to geographical distance, cultural differences do not contribute significantly to the explanation of variability in genetic

Fig. 1 Empirical relationship between normalised gene identity and geographical distance (km) as studied from seven Chilean Indian tribes.

distances. The high correlation between culture and geography may also be interpreted from historical evidence, for within these populations geographical proximity was the only way of establishing cultural contact in the past. Furthermore, the material culture described here is not independent of ecological niche, especially because cultural distances are computed from information which includes subsistence.

A final observation is worth noting. Some researchers claim that a joint consideration of the linguistic and geographical divergencies at times indicates the presence of selective pressures, for example, linguistically distant but geographically close groups showing a great deal of genetic identity may be an indicator of selection as an evolutionary force³. In view of my analysis, such statements seem to be premature, for linguistic divergence can be the result of only recent historic developments of such tribal groups, whereas genetic differentiation by gene frequency changes is known to be a very slow process. Furthermore, in close proximity, exchange of a few mates between populations can never be ruled out. Theoretical predictions reveal that such migration need not be great to bring two neighbouring populations genetically close together¹⁶.

Undulatory swimming with and without waves of contraction

IT HAS been accepted generally that the waves of bending observed in swimming vertebrates are produced by contraction on the concave side of each bend of the body at any point within the cycle of movement¹⁻³. "Waves of contraction" are imagined to pass down the serial myotomes with the velocity of the propagated bends. Another concept, designed primarily to explain snake locomotion⁴, differs by a 90° shift in the timing of contraction on the bending wave, accounting for propulsion but resulting in illogical analysis of fish movement⁵. The former interpretation gives no explanation of the source of locomotory thrust, assuming falsely that the muscular activity required for a given body position is similar whether the position is held or passed through in locomotion. The dominant responsibility of locomotory activity is the propagation rather than the formation of bends, but how is propagation achieved against external resistance? Relevant electromyography of spinal

dogfish^{6,7} has not been related to this mechanical problem. I present here a preliminary report of electromyographic studies of developmental stages of the palmate newt, *Triturus helveticus* (Razoumowsky), and adult tench, *Tinca tinca* L., which show that undulatory propulsion in some animals does not involve waves of contraction and that the "waves" recorded in others function in reducing lateral oscillation anteriorly and adapting tail flexibility to different swimming speeds.

From the time when swimming by waves of bending is first possible in the newt embryo until the time of normal hatching there is no longitudinal delay in muscle activity along the body during the tailbeat. The electromyograms suggest that only the anterior myotomes are used (not those in the tail nor, at first, those in the lower trunk) and these contract together on either side (Fig. 1a). Recent ultrastructural studies have suggested that there is some electrical couplings between myotomal muscle fibres in amphibian embryos which persists for a short time after the development of swimming⁸⁻¹¹. Such coupling may be involved in the synchronisation of contraction along the trunk. The boundary between myotomes which seem to be active and those which seem to be inactive in swimming moves slowly back to the junction of trunk and tail by the end of embryonic life. But the inactivity of the more posterior myotomes survives the development of the capability for involvement in struggling movements, suggesting that it is a functional rather than merely a developmental feature.

The mechanics of this form of locomotion are easy to understand in outline from the simple oscillation of a flexible plate under water. Bending moments can be genera-

Fig. 1 Electromyograms of swimming activity in *T. helveticus*, recorded with 25- μ m diameter wire electrodes (tip position indicated on the left). a, (Monopolar) from a stage-37 embryo, 7.4 mm long; b and c, (bipolar) from a stage-55c larva, 29 mm long (see ref. 8 for developmental stages). In the thinner embryo the contralateral muscle activity is recorded at about half the amplitude of that from the side in which the electrodes are implanted. In the larva the contralateral activity is of much lower amplitude in the recordings. In (a) each of the large amplitude, spike-like events corresponds to a beat of the tail to the right, each of the lower amplitude intervening events to a beat to the left. There seems to be no delay in the occurrence of muscle activity down the length of the body comparable with that in (b) where there is a clear delay in the arrival of activity at electrode q after its cessation at electrode p. c, Violent swimming activity in the same animal, with a return to simultaneity except in the last, low amplitude beat. (The vertical gain on the trace from electrode p is five times that on the other traces which correspond to the scale-bar.)

Fig. 2 Two series of tracings from ciné film of the swimming of *T. helveticus*: *a*, from a stage-37 embryo; *b*, from a stage-55c larva. Both sequences were filmed at 64 frames per s and the frame numbers for each sequence are given. Separation of each position from the baseline represents real movement in space. Each position has been displaced to the right from the preceding one by a fixed distance perpendicular to the baseline (shown by the scale divisions). The reduction of the oscillation of the head axis in (*b*) is indicated by the arrows showing the extreme positions at frames 4 and 6. The limbs have not been drawn in (*b*). The lengths of the animals are given in Fig. 1.

ted anteriorly and conducted along the tail by passive elastic tension. The form of the propagated waves will then depend on the animal's structural characteristics—particularly its flexibility and lateral hydrodynamic resistance—and their longitudinal distribution. The presence of a fin around the tail facilitates the development of both high flexibility and high lateral resistance in that region. These characteristics, combined with muscular passivity, can be seen to be responsible for the whip-like behaviour of the oscillated tail. In this early form of swimming the longitudinal axis of the head may swing through as much as 120° in the horizontal plane within the swimming cycle. During embryonic life the rotation of the head axis is reduced slightly (Fig. 2*a*) but is still measured in tens of degrees.

Early in larval life the myotomal contractions begin to show longitudinal delay, the propagation of some kind of "wave" (Fig. 1*b*). The characteristics of this wave are widely variable, as is the swimming behaviour of the larva, and in the most violent swimming the wave phenomenon is replaced by simultaneity of contraction along the myotomes (Fig. 1*c*). Associated with the wave of contraction is the reduction of the oscillation of the axis of the head to only a few degrees (Figs 2*b* and 4). In the newt larva, violent, "longitudinally simultaneous" swimming is accompanied by a return to wide lateral oscillation of the head.

The wave phenomenon is more easily studied in a larger animal. The electromyogram of the tench in Fig. 3 shows that the delay in the initiation of muscle activity down the body is about twice that of the cessation. This means that the 'burst' of activity becomes shorter, moving caudally along the animal. There is also a period within each half-cycle of movement in which muscle activity is recorded simultaneously over the major part of the myotomal column. If the electromyogram is compared with the movements of the

animal (Fig. 4), periods of simultaneous lateral activity correspond with what may be called the S position of the body, the point at which conventional theory would least predict it. The contralateral overlap of activity occurs in those parts of the cycle in which the fish is approaching the C shape which is fully realised in the swimming of the newt embryo (Fig. 2*a*), but not quite achieved in the swimming of the tench (or the gentle swimming of the larval newt—Fig. 2*b*).

So although waves of contraction are not necessary merely for the propagation of waves of bending, they are recorded in the adult swimmer and they require an alternative explanation. The early initiation of contraction on one side of the anterior trunk, while the tail is still moving towards the other side, prevents the full lateral deflection of the head (Fig. 4). A similar effect is achieved by the newt larva in Fig. 1*b* with early relaxation anteriorly without contralateral contraction. This reduction of anterior movement may have a hydrodynamic significance¹², and certainly will have a behavioural significance in stabilising the cephalic sensory reception during locomotion, particularly in animals which hunt active prey.

In combination with this anterior function of the wave is the more complex concern with providing for various frequencies of tailbeat. The passive tail of the embryo would only function properly over a narrow range of frequencies suited to its mechanical characteristics, and this seems to be all that it is required to do. The embryo swims only at relatively high frequencies (usually 15–25 Hz). The activity of the tail muscle of the more developed animal has to alter the mechanical properties of the tail for wave conduction at different frequencies, for different frequencies entail different lateral velocities and accelerations, which in turn require different bending moments to be generated in the tail if the effective waveform is to be maintained. To do this economically, the mechanical properties of the tail must be suited for passive conduction of waves at the lowest frequencies required (perhaps 1 or 2 Hz) and then be 'stiffened'

Fig. 3 A 1-s portion of electromyogram from a free swimming tench during moderately fast cruising, recorded with six bipolar wire electrodes. The four forward electrodes were close under the skin, those in the tail peduncle (*c* and *f*) were deeper (so that they show something of the contralateral activity). The electrode tip positions are indicated on the left. The frame numbers of the horizontal axis refer to the ciné film which is partly traced out in Fig. 4. There is a delay of about 1.0 s m^{-1} in the initiation of muscle activity down the body, which is about twice the delay in its cessation (about 0.5 s m^{-1}). The overall length of the fish was 16.5 cm.

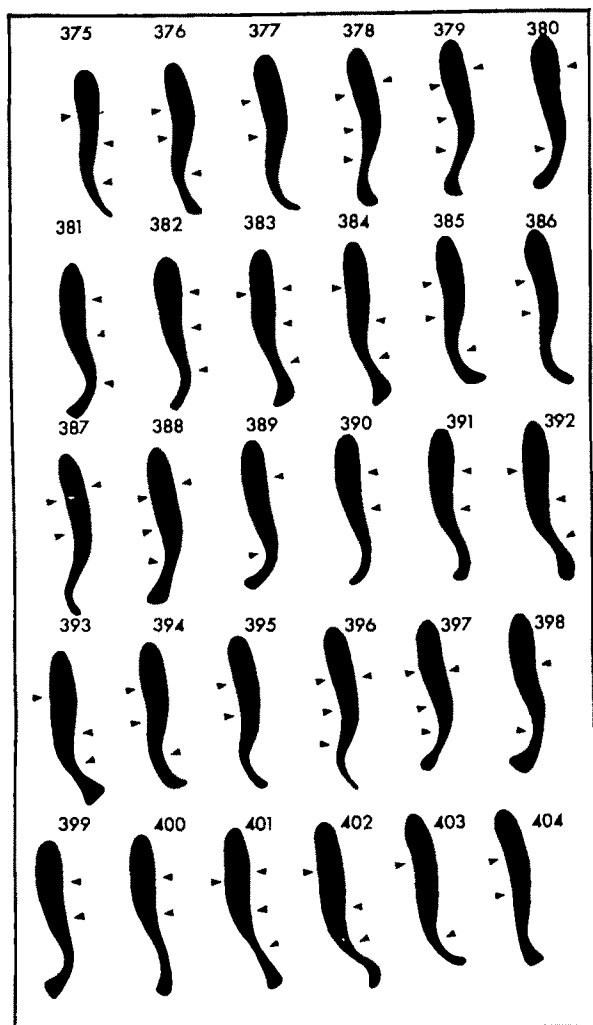

Fig. 4 A series of tracings from ciné film of the swimming of the adult tench electromyographically recorded in Fig. 3. The frame numbers above each position correspond to the scale given in Fig. 3. The arrowheads indicate the approximate sites of electrodes which were showing electrical activity in the muscle at the time of exposure of the film. (The form of the fish is at times slightly distorted by disturbance of the water surface.) The S position of the swimming cycle is characterised by activity only on one side or all down one side. The occurrence of contraction at the anterior of one side and the posterior of the other is associated with the approach of the tip of the caudal fin to its extreme lateral displacement. This condition is often preceded by activity recorded anteriorly appearing on both sides simultaneously. Camera speed was approximately 64 frames s^{-1} .

by muscular contraction during faster swimming movements. In this way the level of muscle activity is directly proportional to speed, rather than inversely, as would be the case if the tail were mechanically suited to the highest speed and actively flexed for lower frequencies. When these adaptations are incorporated, the wave of bending is produced partly passively, partly actively, and the role of the wave of contraction becomes complicated by involvement in modification of the propagation of the bend for the subtle control of movement.

This work was carried out in the Department of Zoology, University of Bristol, and supported by the SRC. I thank Drs Q. Bone, A. Roberts, and H. P. Whiting for discussion.

Effect of caffeine on coffee drinking

CAFFEINE is one of the world's most widely-used drugs and coffee drinking is a major form of its use¹. The levels of caffeine intake in coffee drinking have significant, predominantly stimulatory, physiological and behavioural effects². Surprisingly, the role of caffeine in the self-administration of coffee has not yet been studied. This research indicates that coffee drinkers drink more low-caffeine coffee than non-decaffeinated coffee.

In study 1, Instant Maxwell House Coffee (3.44% caffeine) and Instant Sanka Brand 97% Caffeine Free Coffee (0.14% caffeine) were mixed to produce doses of 100, 50, and 25 mg per cup of coffee. The coffees were packaged in individual-serving foil pouches of 2.94 gm. To avoid severe withdrawal symptoms (headache, fatigue or irritability)^{3,4} and to provide the possibility of maintaining normal caffeine consumption, smaller caffeine doses were avoided. (About 33 cups of decaffeinated coffee are needed to give 100 mg caffeine—the non-decaffeinated dose.)

Subjects were told that they would be receiving different types of coffee without additives. The study took 3 d for each subject—a day on each caffeine dose. The order of presentation was balanced. Daily, subjects received a generous, counted supply of coffee packets and a short questionnaire to assess how they were feeling and how the coffee tasted (good–bad, weak–strong, bitter–sweet, on four-point bipolar scales). Unused and used packets were to be returned. A count of the packets gave a check on reports of coffee intake. Consumption of other coffee, any tea, cola drinks, cocoa, chocolate and certain headache preparations was forbidden: all contain caffeine.

The volunteer subjects (seven females, five males) had an average age of 41 (range: 27–66) and by pre-experimental reports drank 4.5 cups of coffee per day (range: 3–6.5).

Table 1 shows a tendency for coffee intake to increase as caffeine content decreases. Subjects did not 'taste' the caffeine manipulation ($P > 0.5$). Changes in an index of how well the subjects were feeling (by self-report) correlated with changes in coffee consumption. The increased intake

Table 1 Average coffee intake (cups per person) as a function of the caffeine content of the coffee in three studies (\pm s.d.)

Study	Caffeine content (mg)		
	100	50	25
1	4.1*	5.0*	4.5
	± 1.2	± 1.7	± 1.1
2	1.2††	2.0†	2.1†
	± 0.43	± 0.06	± 0.06
3	2.6§	3.0§	3.1
	± 0.09	± 0.19	± 0.15

Means with same superscripts are different by two-tailed *t* tests, $P < 0.05$. In study 1, *t* tests for correlated samples were used; mean combined 50- and 25-mg intake was greater than 100-mg intake, $P < 0.05$; the unexpected quadratic trend, $F(1,22) = 6.10$, $P < 0.05$, may arise from debility from headaches in three subjects on 25-mg caffeine; if they are excluded, the trend disappears and 25- and 50-mg coffee intake becomes almost identical. In studies 2 and 3, *t* tests for independent samples are used for a rough estimate of statistical significance⁵.

of 50-mg relative to 100-mg coffee was associated with increased well-being ($r(10) = +0.70$, $P < 0.02$), the decreased intake of 25-mg relative to 50-mg coffee was associated with decreased well-being ($r(10) = +0.67$, $P < 0.05$).

Studies 2 and 3 treated an institutional coffee pot as the 'subject' in a single subject experiment. If the drinkers comprise constant groups, then the rate of emptying the pots—as a function of caffeine doses—is a valid measure of caffeine's effect on coffee intake.

Study 2 lasted from 0800 to 1100—the 'breakfast pot'—on Wednesdays and Thursdays for 4 weeks on a 40-cup coffee pot located in the dining room of a university hall of residence. There were about 12 regular coffee drinkers (six males, six females—all undergraduates). Roast and ground Maxwell House Coffee and Sanka Brand 97% Caffeine Free Coffee were mixed to yield 100-, 50-, and 25-mg caffeine doses per cup of coffee (week 1=100, week 2=50, week 3=25, and week 4=100 mg). The coffee left in the pot was measured with a ruler. Table 1 shows the estimated average coffee intake per person (each person weighted equally).

Study 3 used the 70-cup coffee maker used by ~ 25 secondary school teachers (~ 66% are female). The study lasted 3 weeks (week 1=100, week 2=25, and week 3=50 mg), from 0800 to 1200 on Tuesdays, Wednesdays, and Thursdays. Subjects were not asked to change their usual drinking habits: many had coffee before coming to work. Table 1 shows the results (adjusted for teacher absenteeism).

These studies were combined by transforming the results to standardised (or z) scores, see Fig. 1. Caffeine is shown to be a determinant of the frequency of coffee consumption. Though the regulation of caffeine intake is far from perfect (total caffeine intake decreases), it is impressive, on considering a few factors. Habits of intake may be slow to

change. Coffee drinking is also water drinking: water regulatory systems could prevent increases in fluid intake. Perhaps non-decaffeinated coffee provides surpluses of caffeine, such that 50-mg coffee ('half-caffeine' coffee) with only small increases in consumption is able to satisfy actual caffeine needs⁶. Too small doses of stimulants have been known to not sustain self-administration⁷: this may explain the failure of 25-mg coffee to be consumed more than 50-mg coffee. A half-caffeine mixture might be recommended to those who are trying to cut down on caffeine intake, but who still desire some of the benefits of caffeine.

Fig. 1 Standardised coffee intake scores (mean = 0, s.d. = 1) on average number of cups of coffee drunk per person as a function of caffeine content of coffee (log scale). Each study was standardised separately, and the range is indicated. The caffeine manipulation influenced coffee intake ($F(2,4) = 16.01$, $P < 0.02$). 50-mg coffee intake was greater than 100-mg coffee intake, $P < 0.02$; 25-mg intake was greater than 100-mg intake, $P < 0.05$; 50- and 25-mg coffee intake did not differ.

Vaccination against bovine tropical theileriasis (*Theileria annulata*)

SINCE the reports of Tsur¹ and Brocklesby and Hawking² on the multiplication of *Theileria annulata* schizonts in spleen explant cultures in plasma clot, the schizonts have been grown successfully for months in tissue culture monolayers^{3–5} and suspension cultures⁶. Successive cultivation of schizonts in tissue culture has been shown to bring about attenuation of the parasite^{7–10}, and suspensions of attenuated schizonts have been used as vaccine to immunise cattle against *T. annulata* in Israel⁴ and Iran¹¹. Reports^{4,11} indicate that the protective effect of the vaccine has been tested against challenge with schizonts but not against the natural tick-induced infection. As there may be some difference in the antigens of schizont and sporozoite (the injected stage of the parasite in the tick), we have evaluated the immunity produced by the vaccine against the infection caused by tick infestation.

Schizont-infected lymphoid cells were obtained by biopsy of a lymph gland of a calf infested with the tick *Hyalomma dromedarii* and infected with virulent Hissar strain¹² *T. annulata*. The cells were cultured in Eagle's MEM (Hanks' base), supplemented with 10% calf serum. Subcultures were made every second or third day and vaccine was prepared from the fifteenth passage.

Crossbred male calves reared in tick-proof rooms were vaccinated when two months old. Fifteen calves were injected subcutaneously at the base of the ear near the parotid lymph node with 1×10^6 schizonts of the fifteenth subpassage. After 35 d, they were challenged with the homologous strain of *T. annulata* by infestation with 10 infective ticks (*H. dromedarii*). The ticks were released on the ear, which was enclosed in a cloth bag. Eight similarly raised susceptible control calves were also infected.

The rectal temperature of the calves was recorded daily. Giemsa-stained smears of blood were examined daily, and of the biopsy material from the regional parotid lymph node

on alternate days beginning a week after the vaccination/challenge. Haemoglobin (Hb) content and packed cell volume (PCV) were determined twice a week.

The reactions to vaccination are summarised in Table 1. Ten of fifteen calves developed fever which commenced between days 13 and 16 and lasted for 1–6 d. The maximum temperature was 40.4 °C. Transient swelling of a regional parotid lymph node was observed in five calves. Parasitised lymphocytes (less than 1%) in the regional lymph gland appeared only in one calf (No. 195) on day 17. Intraerythrocytic piroplasms were observed in 8 of 15 calves between days 17 and 29 for the first time, and later at irregular intervals. Parasitaemia always remained less than 1%. Hb content and PCV of all calves remained normal, and all the calves survived.

When challenged, immunised calves showed no clinical or parasitological reaction, except for one calf (No. 199) which showed less than 1% parasitaemia on day 16. Hb content and PCV remained normal and the blood and regional lymph gland remained free of the parasites. But all eight calves of the control group suffered from the acute type of the disease and six of them died between days 15 and 25 (Table 2). The disease was characterised by high fever which started in 6–11 d, and lasted for 9 d or until death. The intraerythrocytic form of the parasite appeared in 10–13 d. Peak parasitaemias varied from 12 to 80%. The regional lymph gland was swollen in four of eight calves, although infected lymphoid cells (2–25%) were seen in the gland of all the calves.

We conclude therefore that all 15 vaccinated calves became fully immune to the severe tick challenge which killed six of eight unimmunised calves.

The vaccine produced no reaction in five calves and very mild clinical and/or parasitological reaction in the remaining 10, as also observed by Pipano and Israel⁹ with their

10th–15th passage material which at the 50th–120th passage produced no reaction. We are continuing to subculture the parasite with a view to further attenuation.

Non-adaptive rejection of small tumour inocula as a model of immune surveillance

THOMAS's thesis¹ that it is a "universal requirement of multicellular organisms to preserve uniformity of cell type", led him to suggest that the phenomenon of homograft rejection represented the primary mechanism for natural defence against neoplasia. Burnet² viewed this surveillance of lethal oncogenic mutations as a function of the thymus-dependent adaptive immune system. Prehn^{3,4} and others^{5–7} have criticised the Burnet model of immune surveillance because it is unable to account for several important observations: (1) the adaptive

*Tumours obtained from *in vitro* cultures for both primary and secondary challenge.

†Tumours obtained from ascitic passage for both primary and secondary challenge.

‡Appearance of palpable tumour after subcutaneous inoculation.

§All inoculations were 0.1 ml of washed cells. Subcutaneous inoculations were made in mid-low back after removing the fur.

¶After thorough washing, the tumour was resuspended in Fischer's medium containing 15% foetal calf serum. Aliquots of 2.0 ml containing 5 × 10¹ cells were added to 3 ml of 2% Noble special agar at 44 °C. After thorough mixing, the suspension was placed in a 37 °C incubator at 5% CO₂ in a humid atmosphere. Visible clones were counted after 2 weeks in culture. Cloning efficiency was calculated from a minimum of 10 replicates.

**An aliquot of 10⁵ tumour cells in 0.1 ml Fischer's medium was inoculated subcutaneously in the same site as the primary challenge.

††Tumour frequency was assessed 25 d after subcutaneous challenge with the same number of tumour cells as the primary inoculum.

immune system, with only rare exceptions, is unable to eliminate incipient or induced tumours rather than functioning as a surveillance mechanism^{4,5-8}; (2) the immune response to tumours is as likely to result in immunosuppression and enhancement of tumour growth as the destruction of those tumours^{6,9}; and (3) the incidence of spontaneous tumours in athymic mice is insignificant⁸. To explain these data one must either assume that surveillance does not exist, or one must postulate that surveillance exists in a form other than the thymus-dependent adaptive immune response. We have attempted to examine the hypothesis that surveillance exists and is a non-thymus-dependent phenomenon by an experimental model in which the fate of a small tumour inoculum, simulating an oncogenic mutation, is examined after manipulation of the host's immune response.

Several carcinogen-induced tumour lines, the 1509a fibrosarcoma, P-815-X2 mastocytoma and the SL2 lymphoma, as well as the spontaneous lymphoma L5178Y, when implanted subcutaneously in small numbers fail to produce death or a palpable tumour mass in a large proportion of syngeneic recipients (Table 1). To identify the number of injected cells capable of forming a tumour mass, medium containing 50 cells of L5178Y or P-815-X2 was placed in a soft agar gel which allows the formation of single cell clones¹⁰. Cloning efficiencies of up to 46% per inoculum were demonstrated after 3 week of culture (Table 1). The 1509a tumour cells were also shown, in repeated experiments, to grow well *in vitro*. Inocula of 10², 10³ and 10⁴ cells produced 5 × 10⁴, 10⁶ and 5 × 10⁶ tumour cells respectively, in 14 d. The capacity of the small tumour inocula to grow *in vivo* was demonstrated after intraperitoneal implantation of the 1509a, L5178Y and P-815-X2 (Table 1). In spite of the ability of 10² 1509a to grow intraperitoneally, intravenous

as well as subcutaneous challenge with that number of cells produced very few tumours (Table 1).

The rejection of the small subcutaneous inocula, however, could be prevented by the simultaneous intravenous injection of papain digest or 3 M KCl extracts of syngeneic tumour membrane (Table 2). Tumour frequency was 2.5–3.5 times higher than in untreated controls or controls receiving allogeneic membrane at the optimal dose of membrane extract.

The existence of memory was assessed in mice surviving the initial challenge of a small tumour inoculum by rechallenging with a larger tumour dose which was observed in preliminary experiments to result in 100% mortality. The latency and survival rate of mice which had previously rejected the L5178Y and P-815-X2 inocula was no different from that of normal control mice (Table 1). No difference was observed in the survival rates when mice were inoculated with tumour obtained from either *in vivo* peritoneal passage or *in vitro* tissue culture (Table 1). Similarly, mice which had rejected the 1509a in the primary challenge with the small inocula did not reduce either the growth rate or the mortality rate of the secondary challenge. It was also found that mice which had rejected 10² 1509a cells had the same tumour incidence as untreated controls when rechallenged with the same small inoculum (Table 1).

We examined the effects of suppression of the immune response on the incidence of tumours. A/J mice can be made resistant to 1509a by surgical removal of the primary tumour, and the subsequent simultaneous administration of suppressor T cells and 1509a to these immune mice results in enhanced tumour growth⁹. Suppressor T cells given with a small inoculum of 1509a in a primary challenge did not, however, result in any enhancement in the frequency of tumours or their growth rate. In addition, the simultaneous administration of suppressor

Fig. 1 Absence of memory after the rejection of a small 1509a tumour inoculum. *a*, Primary inoculation with 10^3 1509a subcutaneously was followed by a secondary challenge with 10^5 tumour cells 30 d later in the tumour-free mice. Suppressor T cells obtained from A/J thymus⁹ were given intravenously, simultaneously with the 10^5 inoculum in a second group of mice. Control mice did not receive a primary inoculation before 10^5 tumour challenge. The tumour size was measured with a Vernier caliper in two diameters at right angles. Observations were made on five mice in each experimental group. (●) 10^5 1509a secondary challenge after rejection in 10^3 primary challenge; (○) 10^5 secondary challenge after injection of a primary challenge with 10^3 1509a and 4×10^7 suppressor T cells; (■) 10^5 1509a primary challenge. *b*, Experimental protocol is identical to *a* except the primary inoculation is 10^5 1509a.

T cells and the small primary tumour inoculum did not enhance the growth rate of the secondary challenge of 1509a (Fig. 1).

We examined further the question of whether the rejection of small tumour inocula was a thymus-dependent adaptive immune phenomenon by subcutaneously implanting the 1509a and the L5178Y in their respective syngeneic hosts after adult thymectomy, lethal irradiation and bone marrow reconstitution. The frequency of tumours was slightly less in the immunodeficient mice than in the intact control mice, in spite of a much reduced survival rate when challenged with a large tumour dose (Table 3).

If the inoculation of a small number of tumour cells is an adequate model for an oncogenic mutation, the ability of immunodeficient or immunosuppressed mice to reject them suggests that surveillance is not a thymus-dependent adaptive immune phenomenon. This thesis is also supported by the additional evidence that the rejection is not associated with memory.

The ability of syngeneic tumour membrane extracts to

Table 2 Enhancement of tumour frequency after subcutaneous implantation of small tumour inocula by the intravenous injection of syngeneic tumour membrane preparations

*Cloning efficiency of the L5178Y was $47 \pm 5\%$ per inoculum.

†AT×BM mice received 800 rad irradiation 4 weeks after adult thymectomy followed by 2.5×10^7 washed bone marrow cells intravenously. Mice were challenged with tumour 3–4 weeks later.

‡Tumour frequency was assessed at 30 d after inoculation of tumour.

§ $P < 0.001$

enhance tumour frequency suggests that the failure of tumour growth is due to a rejection mechanism with at least some specificity. It is also clear from our observations that one of the features characteristic of this mechanism is the rapidity of its response, acting well before the tumour has reached a critical size. Since tumour growth is very rapid and the time required to reach this critical size is theoretically very small, it suggests that the recognition mechanism is functionally optimal in the normal animal and capable of acting before an adaptive immune response can be generated. Such pre-existing specific immune mechanisms have been identified in two forms in mammals: naturally occurring antibodies^{11,12} and naturally occurring cytotoxic cells^{13–18}.

Natural antibodies with specificity for spontaneous or carcinogen-induced tumour, such as were used in the present study, have been found in normal mouse sera as well as sera from congenitally athymic (*nu/nu*) mice and are predominantly IgM^{14,16}. The role of IgM in anti-tumour immunity is not entirely clear, but it has been implicated in cell-mediated immunity to murine sarcoma virus¹⁷ and tumours induced by mammary tumour virus¹⁸.

Naturally occurring cytotoxic cells have been demonstrated with well defined specificities in *in vitro* assays of tumours immunity^{13–15} and are under genetic control of a strong H-2-linked factor in mice¹⁹. These cells have been partially characterised and bear neither B- nor T-cell membrane antigens^{13,14,20}. Keissling *et al.*²⁰ have also recently demonstrated a correlation between *in vitro* cytotoxicity by naturally occurring cytotoxic cells and their ability to produce *in vivo* neutralisation of an MSV lymphoma in a Winn assay. It is not clear at this time whether mice possess these effector cells in sufficient heterogeneity to account for the recognition of the diverse populations of tumours expected as a consequence of carcinogen-induced mutations, viral transformation, or tumour induction by other oncogenes. But the possibility that these effector cells are responsible for the rejection phenomenon we have observed must certainly be entertained.

We believe, therefore, that if immune surveillance of tumours exists, the possibility that it functions as a thymus-independent, non-adaptive phenomenon must be considered. Although the nature of this type of a surveillance mechanism is not immediately apparent, its identification may be of considerable importance to tumour biology and immunotherapy.

X chromosome activity in oocytes of kangaroo pouch young

In female eutherian mammals, inactivation of one of the two X chromosomes occurs randomly from cell to cell in somatic tissues¹ but in oocytes (meiotic germ cells) X inactivation does not occur for at least three loci. Oocytes of adult XX mice possess twice as much activity as those of XO mice for the sex-linked enzyme, glucose-6-phosphate dehydrogenase (G6PD)², hypoxanthine guanine phosphoribosyl transferase (HGPRT)³, and phosphoglycerate kinase (PGK)⁴. Furthermore, oocytes of adult⁵ and foetal⁶ human females, heterozygous for G6PD allelic genes, show activity for both fast and slow electrophoretic forms of the enzyme. In female kangaroos (Marsupialia: Macropodinae) inactivation of the paternally derived X chromosome occurs in cells of various somatic tissues⁷ but the question of X chromosome activity in oocytes has not been resolved. We have now examined G6PD expression in ovaries of pouch young known to be heterozygous for the fast and slow forms of the enzyme, and show that only a single X chromosome—the maternally derived one—is active in ovarian cells.

Inheritance of G6PD is sex linked in kangaroos⁸. Crosses between wallaroos (*Macropus robustus robustus*: G6PD-F) and euros (*M.r. erubescens* G6PD-S) produce fertile female hybrids heterozygous for G6PD type. Electrophoresis was carried out on ovaries from six heterozygous pouch young aged between 53 and 60 d *post partum*. This age class has the greatest number of oocytes during ovarian development of *Macropus eugenii*⁹ and we assume the same is the case for *M. robustus*. Graphical reconstruction of cell and tissue distribution from serial sections of an ovary from a 53-d-old pouch young showed that primary oocytes accounted for about 70% of the total ovarian volume, a far higher proportion than at any stage of human ovarian development¹⁰.

Most of the oocytes were in zygotene or pachytene of prophase of meiosis I. Specific staining¹¹ of frozen sections of an ovary from another heterozygous pouch young aged 57 d showed that oocytes had a high level of G6PD activity. Although we have no quantitative data on this point, it seems unlikely that activity levels differ greatly from those in human oocytes at comparable stages of differentiation.

If both alleles are functional in oocytes heterozygous for G6PD and the enzyme molecule is a dimer, then electrophoretic bands should be present in the fast and slow positions together with a stronger intermediate or heteropolymer band. In the ovarian extracts examined, however, only a single band was found occupying the maternal position regardless of the direction of the cross, and there was never any trace of a band in the paternal position (Fig. 1). A brief reference to two of these heterozygotes was made earlier¹².

Fig. 1 G6PD electrophoretic phenotypes (F, fast; S, slow) from ovarian and other tissue homogenates of heterozygous pouch young. In the F/S heterozygote (age: 55 d) and the S/F heterozygote (56 d) the allele of maternal origin is referred to first. The S/S homozygote is used as a control. 1, F/S brain; 2, F/S ovary; 3, S/S ovary; 4, F/S uterus; 5, 1:1 mixture of F/S and S/F kidneys; 6, S/F ovary; 7, S/F oesophagus; 8, F/S oesophagus. Channels 1-4 and 5-8 represent separate gels. Samples were homogenised in an equal volume of lysing solution¹³ and applied on to CelloGel (Chemotron). Electrophoresis was carried out in 0.1 M lithium borate-0.0024 M EDTA buffer, pH=9.0, for 1.5 h with a voltage gradient of 14 V cm⁻¹. The gel stain was that of Rattazzi *et al.*¹¹.

In view of the preponderance of oocytes in the ovaries examined and their relatively high levels of G6PD activity, it seems reasonable to conclude that X inactivation of the allele of paternal origin occurs in these cells. At our level of detection it is most unlikely that gene product, forming bands in paternal and intermediate positions, could go undetected. We consider, therefore, that inactivation of the paternal G6PD allele is a feature not only of female kangaroo somatic cells but also of their early primary oocytes.

In human foetal ovaries, results of electrophoresis of G6PD heterozygotes were interpreted as evidence for a reactivation of the inactive X chromosome of germ line cells near the time of entry to meiosis¹³, rather than at the differentiation of primordial germ cells into oogonia as had previously been suggested¹⁴. Foetal ovaries with numerous

zygotene and pachytene oocytes gave a distinct heteropolymer band but in younger specimens with few leptotene oocytes, the heteropolymer band was weak or not detectable at all¹². Ovaries of heterozygous kangaroo pouch young, in which zygotene and pachytene oocytes were predominant, gave no trace of a heteropolymer band, indicating that if reactivation of the paternal allele occurs in kangaroo oocytes it occurs at a later stage of oogenesis. We are at present investigating adult heterozygote ovaries to establish whether reactivation has occurred by the dictyate oocyte stage.

That reactivation of the paternal allele for G6PD does occur at some time during oogenesis (or during embryogenesis) is supported by kangaroo pedigree data¹³. Progeny derived from G6PD heterozygotes may inherit either allele in an active form, suggesting that both X chromosomes are potentially active, at least at this locus. We assume, as have other workers, that activity states at the G6PD locus represent activity states at most if not all X-linked loci so that inactivation of the paternal allele for G6PD is indicative of inactivation of the paternal X chromosome. The patterns of transcription at other X-linked loci in kangaroo oocytes need to be elucidated to validate the supposition.

Kangaroo pachytene oocytes possess an XX bivalent which is isopycnotic with the autosomal bivalents. Air-dried preparations showed no differential condensation of either homologue or regions of homologues. There is thus no cytological evidence of a difference in genetic activity between the maternal and paternal X chromosomes of the kangaroo sex bivalent.

The mechanisms which control the maintenance of X inactivation early in oocyte differentiation and the onset of reactivation at some later stage are not known and are worthy of investigation in the more general context of regulation of activity states in chromosomes.

We thank Drs D. W. Cooper and D. A. Briscoe for discussions and for reading the manuscript, Mr Ron Moore for technical assistance and we also acknowledge financial support from the Australian Research Grants Committee and Macquarie University Research Fund.

Mutagenesis and transformation of normal cells by chemical carcinogens

TREATMENT of normal cells¹⁻⁶ or some established cell lines⁷ in culture with chemical carcinogens can result in cell transformation and malignancy. Cells which have an oriented

pattern of cell growth, a limited life span *in vitro* and are not tumorigenic *in vivo*, are then converted into cells with a hereditary random pattern of cell growth, an ability to grow continuously in culture and to form tumours *in vivo*. Studies with a variety of polycyclic hydrocarbons and other chemicals have shown a correlation between the frequency of colonies with a hereditary random pattern of cell growth (transformed colonies) and the degree of carcinogenicity in animals^{2,6,7}.

The analysis of cell transformation by benzo[a]pyrene, a prototype and most common carcinogenic polycyclic hydrocarbon, has indicated that transformation by this carcinogen is a one-hit event⁸. This one-hit response and the observation that carcinogens can bind to cellular DNA^{9,10} suggest that transformation may result from a single alteration in the genetic constitution of the treated cell. Carcinogens may, therefore, transform cells as a result of a somatic mutation. It has indeed been found that chemical carcinogens can produce somatic mutations at various genetic loci¹¹⁻¹⁵ and that there is a relationship between the degree of carcinogenicity and mutagenicity with different chemicals¹²⁻¹⁵. The relationship between carcinogenesis and mutagenesis in these studies was not, however, tested with the same cells, nor was mutagenesis by environmental carcinogens tested with normal diploid cells.

To elucidate the mechanism of carcinogenesis, it is important to determine the number of the same or different genes which may be involved in cell transformation. The frequency of cell transformation and mutagenesis of specific loci can both be tested *in vitro*. We have, therefore, now carried out experiments with normal diploid cells to determine whether the ratio between transformation and mutation of a specific locus is small, about 10, or large, more than 10³. We have determined mutation and transformation frequencies in primary cultures of normal golden hamster embryo cells treated with the carcinogenic hydrocarbon benzo[a]pyrene and its metabolite 7,8-trans-dihydrodiol¹⁶. The frequency of transformed colonies has been compared with the frequency of mutation for ouabain resistance, a mutation associated with the surface membrane Na⁺/K⁺ ATPase^{16,17}. This mutation was chosen because of its low spontaneous frequency and the ease with which it can be detected in normal diploid cells¹⁷. The cells were treated in the same way to test for the frequencies of transformation and ouabain-resistant mutants.

The results have shown that benzo[a]pyrene and its 7,8-dihydrodiol can induce both transformation and mutagenesis for ouabain resistance in normal diploid cells. The ratio between transformation and mutagenesis for ouabain resistance was about 20:1 with both hydrocarbons (Table 1). Other studies with normal hamster embryo cells treated with benzo[a]pyrene, have indicated a transformation-to-mutation ratio of about the same order of magnitude (J. C. Barrett and P. O. P. Ts'o, personal communication). Since ouabain resistance is presumably due to mutation at one locus¹⁷, it can be suggested that transformation as measured by the appearance of colonies with a random pattern of cell growth has a target equivalent to about 20 such genes. There may thus be this number of the same or different genes, the mutation of any one of which is the single hit required for transformation. Further studies with other genes can determine whether some genes show a lower or higher transformation-to-mutation ratio and whether this ratio changes with different types of carcinogens. The number of genes involved in transformation may be even smaller than about 20, if the genes for transformation are located at hot spots¹⁸ which have a higher mutation frequency. It is of interest that genes which determine the production of altered heavy chains of immunoglobulin in mouse myeloma cells also have a high mutation frequency^{19,20}, of the same order of magnitude as the frequency of cell transformation.

Table 1 Transformation and mutagenesis by benzo[a]pyrene and its 7,8-dihydrodiol

Hydrocarbon	Concentration ($\mu\text{g ml}^{-1}$)	Cloning efficiency (%)	No. of transformed colonies per no. of colonies counted	No. of transformed colonies per 10^6 colony-forming cells	No. of ouabain resistance colonies	A/B
				(A)	(B)	
None	—	12.5	0/6,736	—	0.04	—
Benzo[a]pyrene	1	1.2	16/3,753	4,300	213	20
7,8-dihydrodiol	0.1	2.6	25/5,309	4,700	193	24
	0.3	1.3	18/2,203	8,200	451	18
	1.0	0.9	20/3,183	6,300	419	15

Three- to five-day-old primary normal golden hamster embryo fibroblasts were seeded at 1.5×10^6 cells in 8 ml Eagle's medium with a four-fold concentration of amino acids and vitamins (H-21, Grand Island) with 10% foetal calf serum in 100 mm tissue culture (Falcon) Petri dishes. One day after seeding, the cells were treated for 3 d with benzo[a]pyrene or its 7,8-dihydrodiol metabolite dissolved in a final concentration of 0.5% acetone. The cells were then washed with medium, dissociated with trypsin solution and seeded to determine the frequency of transformed and ouabain-resistant colonies. To test for transformation the treated cells were seeded as described¹⁻³ and the number of colonies counted 10 d after seeding. To test for ouabain resistance¹⁴⁻¹⁷, the carcinogen-treated cells were seeded at 10^6 cells per 50 mm Petri dish. Two days later ouabain was added at a final concentration of 1 mM and the number of colonies counted after 18 d. In all experiments colonies were counted after staining with Giemsa. The data presented are the total results of four separate experiments per point. At the plateau concentration, there was up to about a fourfold variation in the assays for transformed and ouabain-resistant colonies. The heritability of the ouabain resistance was shown with five isolated ouabain-resistant colonies, all of which remained resistant to the drug after 10–12 d growth in the absence of ouabain.

We suggest that cell transformation is due to a mutation and that this mutation can occur in one out of a small number of the same or different genes. Cell transformation by chemicals resulting in a hereditary random pattern of cell growth is an initial step in the process that can result in the formation of tumours^{4,5}. In addition to the mutation resulting in transformation, it also seems that there can then be other genetic changes such as the selection of specific genes that control the ability of cells to form a tumour²¹⁻²³.

Dipole potential measurements in asymmetric membranes

We report here detection of two kinds of asymmetry in planar lipid bilayers which may bear on the problem of asymmetry in biological membranes. One kind of asymmetry arises as a consequence of an asymmetric distribution in the bilayer of lipids with charged polar head groups, and the other from an asymmetric distribution of lipids with different but neutral polar

head groups. Several studies indicate that the lipids of the red cell membrane are asymmetrically distributed. In the erythrocyte membrane the outer half of the bilayer consists predominantly of neutral lipids, whereas the inner half contains all the negatively charged phospholipid phosphatidylserine¹⁻³. In nerve axons such lipid asymmetry has not been demonstrated directly but can be inferred from surface charge measurements. These measurements indicate that at least in the neighbourhood of the sodium channel, the negative charge density is greater in the outer monolayer of the membrane^{4,5}.

Recently it has been shown that lipid redistribution between the two halves of the bilayer is a very slow process⁶⁻⁸, thus indicating that membrane asymmetry can be a stable characteristic of biological membranes. A natural consequence of lipid asymmetry in membranes is a difference in surface potentials. In appropriate conditions this difference can have a major role in controlling ion transport^{9,10}. A surface potential may arise either from ionised groups or from oriented dipoles at the membrane surface or both, and there were indications that the dipole contribution is such that the membrane interior is >300 mV positive with respect to the external solutions¹⁰. Surface charge usually makes the membrane more negative with respect to the solutions. In previous work we showed that surface charge asymmetry in bilayer membranes can be detected and measured using the nonactin-K⁺ complex as a probe⁷. Here we report a similar measurement of the dipole potential difference between two lipids with different but neutral polar head groups. The potential measured in this case does not arise from surface charge, but from a difference in dipole moment per unit area in the two lipid monolayers which form the membrane.

The technique used to form asymmetric bilayers by apposition of the two separate monolayers has been previously described^{7,11}. In the present experiments one monolayer was formed from bacterial phosphatidylethanolamine (PE, Supelco, Inc.) and the other from 1,3 Diolein (GDO, Applied Science Lab., Inc., 99 per cent+) or bovine phosphatidylserine (PS, Supelco). The aqueous solutions in both compartments were equal and consisted of unbuffered (pH ~ 6) KCl solutions of indicated concentration. Nonactin (E.R. Squibb) was added to both compartments in concentrated ethanolic solution; the dilution was usually by a factor of 10^3 . Electrical measurements were made using Ag/AgCl electrodes in a four electrode system¹². Current-voltage curves were directly recorded on an X-Y recorder. The rate of change of voltage was 10 mV s⁻¹ or less to avoid hysteresis. All the experiments were made at $20 \pm 2^\circ\text{C}$.

Figure 1 shows a steady-state current-voltage curve of an asymmetric bilayer membrane in which one monolayer is made of GDO and the other of PE. The voltage is defined as positive

Fig. 1 Steady-state current-voltage curve for an asymmetric membrane made of GDO and PE. Nonactin concentration 2×10^{-8} M. 1 M KCl unbuffered ($\text{pH} \approx 6$). Temperature 21°C . Positive current is defined as flowing from the high dipole potential side (PE) to the low dipole potential side (GDO). The insert shows the data plotted on a logarithmic scale. Note the change in slope for current flowing from the GDO side to the PE side for negative potential in the upper curve. The lower curve is for positive potentials and current flowing from the PE to the GDO side.

when current flows from the PE side across the membrane to the GDO side. The rectification shown by the current-voltage curve is consistent with a more positive dipole potential on the PE side. This rectification arises as a consequence of the actual energy barrier to transport inside the membrane, but it is easier to understand with the trapezoidal approximation shown in Fig. 2. We have previously shown that for large applied voltages a trapezoidal approximation of the actual barrier profile is adequate to describe the steady state current-voltage curves in bacterial PE membranes¹³ as well as those found in asymmetric membranes made of bacterial PE and phosphatidylserine⁷. Figure 2a shows the trapezoidal approximation for the energy barrier profile expected for an asymmetric membrane with a difference in dipole potential, $\Delta\phi$, across it. Studies made in

both monolayers¹⁰ and symmetric bilayers^{10,14} indicate that $\phi\Delta$ between GDO and PE is ~ 100 mV, the interior of a PE membrane being more positive. As shown in Fig. 2b the rate limiting energy for the currents in the positive direction, ϕ_{PE} , is reduced by a positive voltage, nV , where n is the fractional distance to the corner. On the other hand, the rate-limiting energy for the current in the negative direction, $\phi_{\text{GDO}} + \Delta\phi$ in Fig. 2c, is reduced by a negative voltage, $(1-n)V$. Accordingly, the currents in the positive and negative potentials at large voltages must be proportional to $\exp(neV/kT)$ and to $\exp[e(1-n)V/kT]$ respectively, and we would expect a difference in the functional dependence of the current on voltage for different sign of applied voltage like the one shown in Fig. 1. Differences in dipole potential can be calculated with ~ 5 -mV accuracy from the differences in functional dependence of the current on voltages of different polarities. The insert of Fig. 1 shows the logarithm of the current against voltage. The upper curve in the insert represents current flowing from the GDO side to the PE side and the lower curve the reverse current. Both curves diverge until a voltage at which the upper curve changes its slope and becomes parallel to the lower curve. At this point in voltage the external applied potential has compensated exactly for the differences in dipole potential between the two lipids. The calculated difference in dipole potential is 107 mV in 0.02 M and 101 mV in 1 M KCl. It is important to point out that no rectification in the current-voltage curve is expected from a triangular barrier, a shape frequently assumed in the study of carrier mediated transport.

We previously reported⁷ asymmetry in membranes formed with one monolayer of PE and the other of PS. Figure 3 shows the change with ionic strength in the surface potential difference of both PE-PS membranes and PE-GDO membranes. The PE-PS membranes show an asymmetry which depends on ionic strength as predicted on the Gouy-Chapman theory. The asymmetry of PE-GDO membranes is, however, independent of ionic strength. This observation is in agreement with the fact that PE and GDO are neutral at the pH used ($\text{pH} \sim 6$). This lack of change in surface potential with a change in ionic strength is an important characteristic of surface potentials arising from dipoles rather than surface charge.

Differences in dipole potential between different lipids have been inferred by measuring and comparing the specific conductance of symmetrical membranes in the presence of non-actin¹⁸ or lipophilic ions⁹. In the absence of space charge and

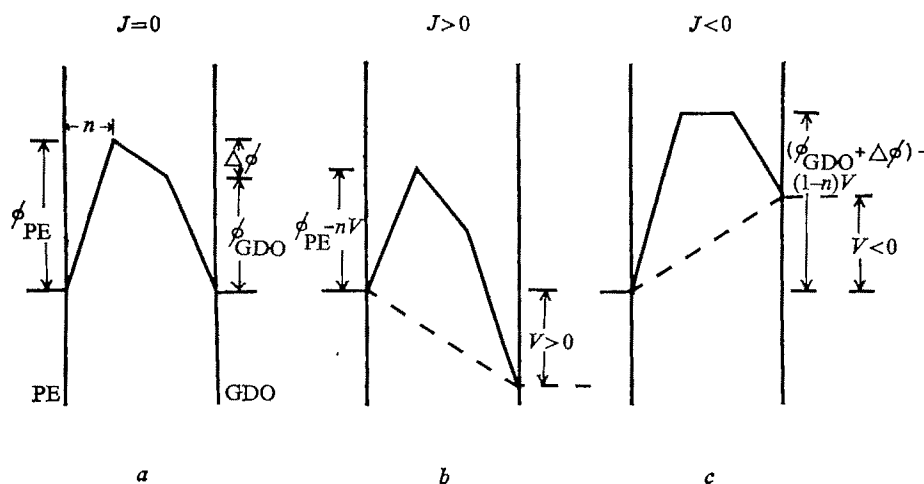

Fig. 2 Schematic representation of the energy barrier of an asymmetric membrane made of GDO-PE. ϕ_{PE} is the barrier height 'seen' by the nonactin-K complexes at the PE side. $\phi_{\text{GDO}} + \Delta\phi$ is the height of the barrier 'seen' by the nonactin-K⁺ complexes at the GDO side. $\Delta\phi$ is the difference in dipole potential between both lipids. n , the fractional distance to the corner, is 0.32 ± 0.03 . a, The expected barrier profile obtained by superposition of the dipole potential profiles for a GDO and PE monolayer. $\phi_{\text{PE}} = \phi_{\text{GDO}} + \Delta\phi$, and therefore there is no net flow of current at 0 potential. b, When a positive voltage V is applied, ϕ_{PE} is reduced by nV and the current flux J is proportional to $\exp(neV/kT)$ for large potentials ($V > 75$ mV). c, The negative potential applied exactly compensates for the differences in dipole potential. By using similar triangles it is easily shown that $\Delta\phi = V/(1-2n)$. Here the barrier height ($\phi_{\text{GDO}} + \Delta\phi$) is reduced by $(1-n)V$ and therefore J is proportional at large voltages to $\exp[e(1-n)V/kT]$. If $V > \Delta\phi/(1-2n)$ then the height of the right hand corner of the barrier will become the current limiting step.

kinetic limitations from the formation of complexes at the membrane surface, the present method provides a way to measure such a difference directly, and does not depend on the nonactin concentration because it measures a difference in shape and not in magnitude. It also allows us to monitor

Fig. 3 Surface potential difference as a function of ionic strength. ●, Asymmetry potentials of membranes formed from one monolayer of phosphatidylserine and one of phosphatidylethanolamine. The dependence of surface potential on ionic strength is very nearly as predicted from the Gouy-Chapman equation with a surface charge density of 1 electronic charge per 75 \AA^2 (shown by the solid line). ▲, Asymmetry potentials of membranes formed from one monolayer of phosphatidylethanolamine and one of glycerol dioleate. The lack of dependence of surface potential on ionic strength is in agreement with a potential arising from dipoles rather than surface charge. Temperature $21 \pm 1^\circ \text{C}$.

changes in membrane asymmetry with time for membranes formed with two neutral lipids as long as they have a difference in dipole potential. Detection of 'flip-flop' in lipids in planar asymmetrical bilayer membranes has been restricted to membranes containing charged lipids^{16,7}. So far we have been unable to detect any lipid redistribution in membranes made of GDO and PE; this confirms other results⁸⁻⁹. It is of interest to note that we have detected no asymmetry in the current-voltage curves of membranes made of glycerolmonooleate and PE, even though the differences in dipole potential are $\sim 120 \text{ mV}$ (ref. 15). A possible explanation is that glycerolmonooleate distributes itself very rapidly between the two monolayers.

We have interpreted the asymmetry of our voltage-current curves as arising solely from differences in surface potential between two lipids. We believe this to be the case for two reasons. First, the asymmetry arising from charged lipids can be unambiguously attributed to a change in electric field across the membranes because of its dependence on ionic strength. Second, our neutral lipid results are consistent with values of surface potential derived from both monolayer and symmetric membrane studies^{10,13,15}.

As previously mentioned, lipid asymmetries are apparently present in many biological membranes. The differences in surface potential brought by the asymmetric lipid distribution can play an important role in affecting various charged structures in the membrane, for example the gating charges in nerves. Our work provides a means of measuring asymmetric potentials in membranes of well defined composition. Our results thus enable us to estimate how lipid composition may affect all electrical functions of biological membranes.

This work was supported in part by the NIH and The Louis Block Fund, The University of Chicago. We would like to thank Mr W. Koroshetz for help with some of the experiments.

The effects of antipsychotics on the turnover rate of GABA and acetylcholine in rat brain nuclei

SEVERAL lines of indirect evidence indicate that the nigrostriatal and mesolimbic dopaminergic systems interact with acetylcholine (ACh)^{1,2} and γ -aminobutyric acid³ (GABA)-secreting neurones. The reciprocal relationships among these neurones have not, however, been established with precision. Nucleus caudatus and nucleus accumbens are innervated by dopaminergic axons which have their cell bodies located in substantia nigra and ventral tegmental area⁴, respectively. These nuclei contain high concentrations of ACh⁵ and GABA⁶ and a high activity of cholineacetyltransferase (CAT)⁷ and glutamic acid decarboxylase⁸ (GAD). The nucleus accumbens and nucleus caudatus are connected with globus pallidus and substantia nigra which also contain GABA⁹, ACh¹⁰ and their synthesising enzymes. Antipsychotics, including chlorpromazine, clozapine and haloperidol increase the turnover rate of dopamine (DA) in the nucleus caudatus and nucleus accumbens¹¹. Clozapine, a non-cataleptogenic antipsychotic, preferentially increases the DA turnover in the nucleus accumbens whereas chlorpromazine and haloperidol, two cataleptogenic antipsychotics show a preferential effect on the nucleus caudatus¹².

We here show that the action of clozapine, chlorpromazine and haloperidol on the turnover rates of ACh and GABA in the nucleus caudatus, nucleus accumbens, globus pallidus and substantia nigra allows for a qualitative differentiation between the biochemical effects elicited by clozapine and cataleptogenic antipsychotics. The results not only shed some light on the possible functional interdependence among GABA, ACh and DA in neuronal systems of single brain nuclei but also they provide some biochemical information which may allow us to predict a pattern of specific neurotransmitter involvement in the genesis of the cataleptogenic effects of antipsychotics.

The turnover time of ACh in nucleus caudatus, substantia nigra, globus pallidus and nucleus accumbens was

measured by infusing phosphoryl (d_4) choline ($15 \mu\text{mol kg}^{-1} \text{min}^{-1}$) at a constant rate, intravenously, for 9 min (ref. 9) and killing the rats at the end of the infusion with a high intensity microwave beam focused on the skull¹⁰. The brain was sliced into 400 μm thick slices and single brain nuclei were punched out as reported earlier⁸. Haloperidol ($10 \mu\text{mol kg}^{-1}$) clozapine ($30 \mu\text{mol kg}^{-1}$) or chlorpromazine ($20 \mu\text{mol kg}^{-1}$) were injected intraperitoneally 51 min before beginning the infusion with phosphoryl (d_4) choline. The deuterium enrichment of choline and ACh was measured by mass fragmentography in various brain nuclei^{6,9}. From these data the time needed to synthesise the ACh present in each nucleus (turnover time) was calculated¹¹. The estimation of GABA turnover time was performed by killing the rats at various times after the constant rate intravenous infusion of D-glucose uniformly labelled with ^{13}C ($50 \mu\text{mol kg}^{-1} \text{min}^{-1}$ for 10 min). Rats were killed with a microwave beam at 2, 3.5 and 5 min after the end of infusion and various brain nuclei were dissected stereomicroscopically as described above. The GABA content was measured by mass fragmentography as reported earlier¹², the turnover time of GABA was calculated from the percentage incorporation of ^{13}C into glutamate and GABA¹³. Haloperidol ($4 \mu\text{mol kg}^{-1}$, intraperitoneally) and clozapine ($30 \mu\text{mol kg}^{-1}$, intraperitoneally) were injected 40 and 20 min respectively, before the infusion with ^{13}C -glucose

Haloperidol, which is virtually devoid of anticholinergic effects¹⁴, reduced the ACh turnover time in the nucleus caudatus and nucleus accumbens, whereas clozapine, which is a potent muscarinic receptor blocker¹⁴⁻¹⁶ failed to change the turnover of ACh in these two nuclei (Table 1). The results obtained with haloperidol and chlorpromazine further support the current belief that nigrostriatal and mesolimbic dopaminergic synapses inhibit the metabolism of ACh in cholinergic postsynaptic-interneurons³. When dopaminergic receptors were blocked by these two cataleptogenic antipsychotics the metabolism of ACh in nucleus caudatus and nucleus accumbens increased (Table 1). Perhaps the decrease of ACh turnover time suggests that the activity of intrinsic cholinergic interneurons of nucleus caudatus and nucleus accumbens was increased. Our findings with ACh turnover time in the nucleus accumbens of rats are at variance with results obtained with push-pull cannulae perfusion of limbic and striatal areas of cats. These results show that cataleptogenic antipsychotics increase the efflux of ACh from striatum but not from limbic areas¹⁷. Since clozapine and haloperidol block the inhibition of striatal ACh metabolism caused by apomorphine¹⁸ it can be inferred that clozapine and haloperidol can block the postsynaptic, dopamine receptors in the nucleus caudatus¹⁸. Moreover, when clozapine was injected in rats receiving haloperidol the metabolism of striatal ACh failed to increase¹⁸. No direct explanation can be given for the different action of clozapine and cataleptogenic antipsychotics on the ACh turnover rate in the nucleus caudatus and nucleus accumbens.

Fig. 1 Turnover time (h^{-1}) of GABA in various brain nuclei. Each bar represent an average of at least five measurements; brackets indicate s.e.m. Open bars, saline treated rats, closed bars, rats injected intraperitoneally with $30 \mu\text{mol kg}^{-1}$ of clozapine 20 min before ^{13}C glucose infusion. Dashed bars, rats treated intraperitoneally with $4 \mu\text{mol kg}^{-1}$ of haloperidol 40 min before labelling. SN, Substantia nigra, GP, globus pallidus; Cau, nucleus caudatus; Acc, nucleus accumbens.

Perhaps as proposed in earlier work¹⁸ an intrinsic positive feedback involving cholinergic synapses is operative; when this positive feedback was blocked by clozapine, the blockade of DA receptors failed to increase the ACh turnover rate in nucleus caudatus and nucleus accumbens.

Evidence is available to show that dopamine stored in dendrites of dopamine cell bodies of substantia nigra¹⁹ can be released by drugs¹⁹. In substantia nigra, the antipsychotics failed to change ACh turnover time (Table 1) suggesting that the blockade of DA receptors did not affect the ACh metabolism in substantia nigra (Table 1). However, cataleptogenic and non-cataleptogenic antipsychotics reduced the ACh metabolism in globus pallidus (Table 1).

Haloperidol and clozapine reduced the turnover time of GABA in globus pallidus and nucleus accumbens (Fig. 1). Both globus pallidus and nucleus accumbens contain high concentrations of GABA²⁰ and high GAD activity⁷. A pool of GABA-secreting interneurons, similar to that in nucleus caudatus⁴, may be present in nucleus accumbens and in globus pallidus²⁰. Since the blockade of DA receptors increased the rate of GABA metabolism in nucleus accumbens (Fig. 1), it is inferred that in this nucleus, DA receptors regulate GABA metabolism trans-synaptically. A similar suggestion can be made to explain the increase in GABA metabolism in globus pallidus because in this nucleus, which is devoid of dopaminergic terminals³, GABA may be stored in terminals from axons

Table 1 Effects of antipsychotics on acetylcholine (ACh) turnover time in various nuclei of rat brain

Brain nuclei	ACh turnover time (h^{-1})			
	Saline	Haloperidol ($10 \mu\text{mol kg}^{-1}$, i.p.)	Clozapine ($30 \mu\text{mol kg}^{-1}$, i.p.)	Chlorpromazine ($20 \mu\text{mol kg}^{-1}$, i.p.)
Substantia nigra (0.11 ± 0.018)	0.43 ± 0.07	0.31 ± 0.1	0.53 ± 0.06	0.63 ± 0.09
Globus pallidus (0.16 ± 0.023)	0.09 ± 0.03	$0.43 \pm 0.05^*$	$0.26 \pm 0.03^*$	$0.42 \pm 0.05^*$
Nucleus caudatus (0.60 ± 0.032)	0.10 ± 0.01	$0.04 \pm 0.01^*$	0.08 ± 0.01	$0.06 \pm 0.005^*$
Nucleus accumbens (0.60 ± 0.061)	0.10 ± 0.02	$0.04 \pm 0.01^*$	0.07 ± 0.01	$0.04 \pm 0.01^*$

Each value is the mean \pm s.e.m. of at least five assays. Drugs were injected 51 min before the intravenous infusion of phosphoryl (d_4) choline ($15 \mu\text{mol kg}^{-1} \text{min}^{-1}$) for 9 min. Numbers in parenthesis are the ACh concentration in $\mu\text{mol per g protein}$ (mean \pm s.e.m.; $N = 5$). i.p., Intraperitoneal.

originating in nucleus accumbens. Haloperidol and clozapine act differently on ACh or GABA turnover in all structures tested except globus pallidus where they reduce ACh metabolism (Table 1) and increase that of GABA (Fig. 1). This increase of GABA utilisation in the nucleus accumbens-pallidal pathway decreases ACh metabolism in globus pallidus probably by a trans-synaptic mechanism.

Clozapine reduced GABA turnover time in substantia nigra and striatum, whereas haloperidol failed to change GABA metabolism in substantia nigra but decreased that of striatal GABA (Fig. 1). Since substantia nigra receives GABA terminals from nucleus caudatus²⁰⁻²³, the increase in the metabolism of GABA elicited by clozapine in substantia nigra and nucleus caudatus may be interrelated. At this time we can only suggest the possibility that muscarinic receptors regulate transmitter metabolism in intrinsic GABA interneurons of striatum and in the strio-nigra GABA neurones.

Indeed a precise interpretation for the mechanisms that are operative in contributing to the difference between the effects of haloperidol, chlorpromazine and clozapine on GABA and ACh metabolism in basal ganglia awaits further investigation; however, it is important to know that an enhanced metabolism of GABA in striatum and substantia nigra is elicited by clozapine, an antipsychotic which blocks DA receptors like haloperidol and chlorpromazine but unlike these two drugs, fails to cause tardive dyskinesias or extrapyramidal side effects^{24,25,26}.

In conclusion, the cataleptogenic antipsychotics decrease the ACh turnover time in nucleus caudatus and nucleus accumbens whereas clozapine does not; the latter decreases the turnover time of GABA in substantia nigra and nucleus caudatus whereas haloperidol does not. One might speculate on the possibility that antimuscarinic and GABA mimetic actions help to limit the cataleptogenic actions of antipsychotics; in contrast a reduction of ACh and an increase of GABA metabolism in globus pallidus express a characteristic change in striatal output elicited by cataleptogenic and non-cataleptogenic antipsychotics. Since globus pallidus includes an important output from nucleus caudatus and nucleus accumbens one might infer that the changes in ACh and GABA metabolism are biochemical responses related to the antipsychotic action which are independent from the extrapyramidal side effects.

Stimulation of pontine reticular formation suppresses firing of serotonergic neurones in the dorsal raphe

THERE is ample evidence¹⁻¹⁰ that both the pontine reticular formation (PRF; including the nucleus reticularis pontis oralis and caudalis in the terminology of Olszewski and Baxter¹¹ or the gigantocellular tegmental field in Berman's¹² terminology) and the brainstem raphe nuclei are involved in sleep processes. We report here that PRF-stimulation suppresses firing in raphe neurones. These results have implications which bear directly on current concepts about the cellular mechanisms involved in the control of the sleep cycle.

Evidence from lesion¹⁻³ and stimulation⁴⁻⁵ studies suggests that the PRF is important in the generation of rapid eye movement (REM) or desynchronised sleep (DS). Hobson *et al.*⁶⁻⁸ have found that cells in the PRF selectively increased their firing just before the onset of DS and maintained their high activity throughout the whole DS episode. On the other hand, McGinty and Harper⁹ reported that cells in the dorsal raphe nucleus (DRN) ceased their firing before the occurrence of pontogeniculooccipital (PGO) waves and their activity remained low during the ensuing DS. The occurrence of PGO waves is thought to be inhibited or 'gated' by the release of 5-hydroxytryptamine (5-HT)^{13,14}. It is possible that immediately preceding the onset of and during the DS episode, cells in the PRF exert an inhibitory influence on cells containing 5-HT in the DRN which, in turn, release the gate or disinhibit the PGO wave activity. Anatomical studies using Golgi¹⁵, Nauta¹⁶, autoradiography¹⁷ and horseradish peroxidase¹⁸ techniques have indicated the presence of projections from the PRF to midbrain raphe nuclei. We have also presented pharmacological evidence¹⁹ suggesting the existence of an inhibitory pathway from the PRF to the DRN. The purpose of this study was to investigate the influence of electrical stimulation of the PRF on 5-HT cells in the DRN and to explore the possible neurotransmitters which might mediate these effects.

Under chloral hydrate anaesthesia (400 mg kg⁻¹, intraperitoneally), 20 male Sprague-Dawley rats (200-300 g) were implanted with concentric stimulating electrodes in at least one, in most cases two, of the following structures: (1) the ventromedial PRF [posterior 1 mm (to lambda); lateral 0.7 mm; horizontal -8 mm (below skull surface)]; (2) the locus coeruleus (LC; P 1 mm; L 1.1 mm; H -6 mm); and (3) the nucleus trigemini principalis (NprV; P 1 mm; L2 to 2.5 mm; H -6.5 mm). Stimulation of the latter two structures served as controls. Electrodes were positioned at an angle of 10° to the vertical so that there was enough space for lowering the recording micropipettes. Micropipettes filled with 2 M NaCl saturated with fast green FCF²⁰ were lowered through a burr hole into the DRN (A 0.5 mm; L 0 mm; H -5.5 to -7 mm). Methods for differential recording of single unit activity during electrical stimulation, drug administration, histological localisation and physiological data analysis have already been described in detail^{19,20}. 5-HT cells in the DRN were tentatively identified by their wave form (that is, a predominant positive then a negative wave) and by their slow, regular spontaneous dis-

Fig. 1 Comparison between the responses of a typical 5-HT cell to PRF-stimulation and control electrode stimulation. This experiment was carried out in a 6-OHDA pretreated (8 d) rat to rule out the involvement of the LC and other adrenergic systems. We gave an intraperitoneal injection of chlorimipramine (1 mg kg^{-1}) to protect the 5-HT system before the intraventricular injection of $200 \mu\text{g}$ of 6-OHDA in $20 \mu\text{l}$ of ascorbic acid solution (1 mg ml^{-1}). *a-c*, Continuous oscillographic records of cellular discharge. The line under the oscillographic record indicates the stimulation period. Each division on the line is 10 s . In *a*, there was no suppression following the stimulation of the control electrode (10 Hz , 0.1 mA , 1 ms pulsewidth) which was located in the NprV. In *b*, PRF-stimulation at 0.05 mA (10 Hz , 1 ms) resulted in a slowing of the firing. In *c*, PRF-stimulation at 0.1 mA (10 Hz , 1 ms) produced a total suppression of cellular activity. Calibration: 0.5 mV . Positivity is upward.

charge rates ($0.5\text{--}2.5 \text{ spikes s}^{-1}$). This firing pattern has been demonstrated by combined single cell recording and fluorescence histochemical methods²² to be characteristic for 5-HT-containing cells but not for non-5-HT-containing cells in the adjacent central grey or reticular formation. Recently, the identification of the slow, regular units in the DRN as 5-HT neurones has been confirmed electrophysiologically: electrical stimulation of the ascending 5-HT axonal pathway in the ventromedial tegmentum of the anterior midbrain produces antidromic responses only in the type of unit described above (ref. 21 and R.Y.W. and G.K.A., in preparation).

Fig. 2 Photomicrograph of a coronal section of the brain stained with cresyl violet showing that in a bilateral LC(*)-lesioned rat, the tract of the PRF stimulating electrode (arrow) is in the nucleus reticularis pontis caudalis.

Electrical stimulation of the ventromedial PRF markedly suppressed spontaneous firing of 5-HT cells in the DRN; in many cases suppression of firing was produced by PRF-stimulation at relatively low frequencies and currents. The term 'suppression' is used in preference to 'inhibition' because we cannot rule out the possibility that the depressant effects of PRF-stimulation on DRN cells are due (indirectly) to disfacilitation. The degree of suppression of the firing of DRN cells was proportional to the strength of the stimulus applied to the PRF (Fig. 1*b* and *c*). Repeated stimulation at 1 Hz ($0.05\text{--}0.2 \text{ mA}$, pulsewidth 1 ms) resulted in a poststimulus period of total suppression lasting $50\text{--}300 \text{ ms}$ in 66 of 68 (97%) typical 5-HT cells. Of these 66 cells, 7 showed an initial excitation preceding the period of suppression. None of the cells ($N = 4$) which lacked the characteristic firing pattern of 5-HT neurones was affected by the stimulation. Most of the 5-HT cells responded to the PRF-stimulation with a short latency of suppression (range, $0\text{--}66 \text{ ms}$; mode 0 ms ; median, 8 ms ; mean $\pm \text{s.e.}$, $10.0 \pm 11.5 \text{ ms}$). By 0 latency ($N = 14$) we mean that the onset of the suppression was so rapid that no spike occurred in between onsets of the stimulation and the suppression of firing. Although the short latency of this effect suggests the existence of a monosynaptic PRF-DRN pathway, a polysynaptic pathway cannot be ruled out by our data. The mechanism of PRF-induced suppression of firing cannot be attributed to recurrent inhibition because none of the recorded raphe cells showed signs of antidromic activation (that is, invariant latency, faithful response to high rate of stimulation and collision to orthodromic spikes). The absence of antidromic responses might be due to the fact that there are only scattered 5-HT terminals in the reticular formation²³.

In four experiments, stimulating electrodes were put into different regions of the anterior medullary reticular formation. In these rats, 5-HT cells ($N = 6$) in the DRN were not suppressed by the stimulation. This suggests that the effects of PRF stimulation are mediated by cells which originate in this

Table 1 Comparison between the response of 5-HT cells to PRF stimulation and to control electrode stimulation

Electrode location	No. of rats	No. of cells suppressed	No. of cells not suppressed	% Suppressed
PRF	18	66	2	97%
LC*	4	4	15	21%
NprV*	9	3	19	14%

PRF, pontine reticular formation; LC, locus coeruleus; NprV, nucleus trigemini principalis.

*Compared to PRF stimulation, the proportion of 5-HT cells suppressed by stimulation of control electrodes is significantly lower ($P < 0.001$, χ^2 test with Yate's correction). The difference between the LC and the NprV groups is not significant.

Fig. 3 PRF-induced suppression of firing of 5-HT neurones and their blockade by intravenous injection of the GABA antagonist picrotoxin. *a* and *b* are two different 5-HT cells from two rats in separate experiments. Activity of neurones was displayed either directly on a storage oscilloscope (cell *a*) or in the form of a peri-stimulus time histogram (cell *b*). Every picture and histogram consists of at least 150 sweeps. The latency of suppression was determined by measuring the time elapsed between the onset of stimulation and the last spike preceding the onset of suppression. Arrows indicate the onset of electrical stimulation. In column *A*, before administration of picrotoxin, PRF-stimulation had a marked effect on 5-HT neurones. In column *B*, after the intravenous injection of picrotoxin, PRF-induced suppression was reduced in cell *a* (2.5 mg kg^{-1}) and was totally blocked in cell *b* (6 mg kg^{-1}). Vertical counts in cell *b* represent number of spikes in each address.

area rather than ascending fibres. This agrees with the anatomical study of Nauta¹⁶ who has shown that the segment of the ascending component of Forel's tractus fascicularum which projects to the midbrain raphe area originates at a more rostral tegmental level rather than from the medulla.

When the stimulating electrode was located either in the LC or in the NprV, there were considerably fewer 5-HT cells suppressed by the stimulation. Table 1 lists the number of 5-HT cells suppressed by stimulation of the PRF, LC and NprV. Compared to PRF-stimulation, the proportion of 5-HT cells suppressed by stimulation of either the LC or the NprV is significantly smaller ($P < 0.001$, χ^2 test); latencies of suppression produced by stimulation of control electrodes (combined LC and NprV group) were longer ($16.5 \pm 15.9 \text{ ms}$ against $10.0 \pm 11.5 \text{ ms}$, $P > 0.05$, two-tailed t test); and current thresholds for control electrodes to elicit suppression of firing on 5-HT cells were much higher ($0.27 \pm 0.06 \text{ mA}$ against $0.09 \pm 0.04 \text{ mA}$, $P < 0.001$, two-tailed t test; Fig. 1a).

To demonstrate further that stimulation of the LC does not contribute materially to PRF-induced suppression, we bilaterally destroyed the LC before the stimulation and recording experiments. Using either radio-frequency lesions or chemical lesions with intraventricular injection of 6-hydroxydopamine (6-OHDA), we have consistently destroyed the LC¹⁹. The extent of the LC lesions was verified by either routine histological methods (Fig. 2) or the Falck-Hillarp type fluorescence histochemical method. As can be seen from Fig. 2, the radio frequency lesion destroyed the dorsolateral part of the PRF as well as the LC. In these LC (and dorsolateral PRF)-lesioned rats ($N = 6$) PRF-induced suppression of 5-HT cells was undiminished; all 15 5-HT cells were readily inhibited by ventromedial PRF-stimulation (Fig. 1b and c).

In an attempt to explore the possible transmitters involved in the PRF-induced suppression, we compared the PRF-induced effect on 5-HT cells both before and after the intravenous administration of the γ -aminobutyric acid (GABA) antagonist picrotoxin or the glycine antagonist strychnine. We found that picrotoxin reduced markedly the PRF-induced suppression of 5-HT cells ($N = 6$). Figure 3 is a representative example showing that picrotoxin reduced PRF-induced suppression at a dose of 2.5 mg kg^{-1} and totally blocked the suppression at a dose of 6 mg kg^{-1} . In contrast, picrotoxin at these dose levels, failed to block the recurrent inhibition of DRN cells produced by stimulation of the ascending 5-HT pathway (R.Y.W. and G.K.A., in preparation). Strychnine ($0.4\text{--}1 \text{ mg kg}^{-1}$, intravenously) had little or no effect on PRF-induced suppression (8 cells). These results are suggestive of a possible role for GABA in mediating the effect produced by PRF-stimulation and are consistent with our previous finding

that 5-HT cells in the DRN are inhibited by local, iontophoretic application of GABA and that this inhibition is blocked by picrotoxin¹⁹.

In conclusion, our data indicate that stimulation of the PRF markedly suppresses the activity of 5-HT cells in the DRN and that this effect might be mediated through a PRF-DRN GABAergic pathway. These results support the hypothesis that immediately preceding the onset of and continuing throughout the DS episode, cells in the PRF, which are known to increase their firing at this time⁶⁻⁸, exert a powerful, inhibitory influence on 5-HT cells in the DRN. On the other hand, we conclude that the LC has a minor and possibly indirect influence on 5-HT cells in the DRN because: (1) stimulation of the LC (which consists of cells containing noradrenaline) does not have a marked inhibitory effect on 5-HT cells in the DRN; and (2) the microiontophoretic application of noradrenaline directly on to 5-HT cells does not consistently produce inhibition^{19,24}. Experiments are now being conducted on behaving rats to eliminate the possible influence of anaesthesia on the response of DRN cells to PRF stimulation. *Note added in proof:* A recent abstract²⁵ agrees with our result that stimulation of LC has a minor and possibly indirect influence on 5-HT cells in the DRN.

Decrease of acetylcholine receptor synthesis in muscle cultures by electrical stimulation

MUSCLE activity has been shown to be a central factor in controlling the level of extrajunctional acetylcholine receptors (AChR): inactivity of muscle fibres causes an increase in the number of AChR and electrically stimulated activity causes a decrease. We investigated the mechanism by which this activity regulates the level of AChR in muscle fibres that have differentiated in cell culture. Our results suggest that electrical stimulation decreases the AChR level by decreasing the synthesis of the receptors rather than by degrading or inactivating them.

In normally innervated muscle, AChR are located at the endplate. After surgical denervation, however, there is a great increase in the number of AChR in the region outside the endplate¹. A clear indication that muscle activity plays a part in controlling the extrajunctional AChR came from the experiments in which an electrically stimulated contraction of denervated muscle suppressed the spread of

Fig. 1 Time course of ¹²⁵I- α -BuTX binding by chick muscle cultures treated with electrical stimulation (\square), or 0.5 μ g ml⁻¹ TTX (Δ). Each point represents the mean of three replicates. The electrical stimulation of the muscle was achieved through a pair of platinum electrodes immersed in the culture medium and fastened 25 mm apart, to a cover glass of the 30 mm dish. Six-second trains of 1 ms square-wave pulses with an interval between pulses of 200 ms were delivered to each dish every minute. Pulse polarity was alternated for each train to prevent polarisation. The voltage was approximately 20 V. Growing of the muscle cells and the determination of the amount of toxin bound were as described before¹⁰.

Table 1 Effect of cycloheximide on AChR

	AChR (fmol per dish)	Half life (h)
Control	219 \pm 20	28 \pm 3
Cycloheximide (20 μ g ml ⁻¹)	231 \pm 16	267 \pm 22
Stimulated	123 \pm 4	26 \pm 2
Stimulated + cycloheximide	224 \pm 14	276 \pm 26

10-d-old chick muscle cultures were treated for 48 h as indicated, then the amount of toxin bound, which reflects the amount of AChR, was measured. To measure the rate of AChR degradation, 14-d-old muscle cells were first pulsed with ¹²⁵I- α -BuTX then the cells were treated as indicated for 3 d. Half life of AChR was determined from the decline of radioactivity bound in the culture dish. Each value is the average of three replicates \pm s.d.

AChR^{2,3}. Furthermore, it was reported⁴⁻⁷ that electrical stimulation of denervated muscle reduced the supersensitivity to ACh.

The reduction in the amount of AChR following electrical stimulation could be a result of: (1) inhibition of AChR synthesis, (2) increase in AChR degradation, (3) inactivation of extrajunctional AChR. To distinguish between these possibilities we used muscle cells grown *in vitro*. Such muscle fibres were found to produce AChR⁸ and also to develop ACh supersensitivity in response to tetrodotoxin (TTX) application, which inhibits their spontaneous activity^{9,10}. When muscle cultures were stimulated electrically, the amount of AChR, as measured by labelled α -bungarotoxin (α -BuTX) binding, was reduced considerably, compared to the control or to the TTX-treated cells (Fig. 1).

The above-mentioned difference between stimulated cultures and those of the control could be explained by a different turnover rate of AChR. Such a difference in the turnover rate of junctional and extra-junctional receptors has been reported^{5,11,12}. To test this possibility, muscle cultures were first pulsed with ¹²⁵I- α -BuTX, then electrically stimulated and the rate of toxin loss was measured (Table 1). If we assume that the toxin loss reflects intracellular degradation of toxin-receptor complex¹³, then the results show that the various treatments had very little effect on AChR degradation rate. (The half life fell within a 26-28 h range.) When protein synthesis was inhibited in the electrically stimulated cultures by cycloheximide, no decrease in the amount of AChR was observed (Table 1). This result is in contrast to the above-mentioned decrease in AChR resulting from electrical stimulation in the absence of protein synthesis inhibitor. This effect of cycloheximide might be explained, as has been suggested^{11,13}, by an inhibition of receptor degradation (Table 1). The fact that there is no decrease in the amount of AChR in the presence of the inhibitor suggests that the electrical stimulation *per se* does not inactivate the receptors.

To measure the effect of electrical stimulation on receptor synthesis, the existing cholinergic receptors were saturated with unlabelled α -BuTX. Then the rate of appearance of new receptors was measured by binding of radioactive α -BuTX after various periods of stimulation. It was reproducibly found that the stimulated cultures bound much less ¹²⁵I- α -BuTX than did the control, or the TTX-treated cultures (Fig. 2). These experiments suggest that the decrease in α -BuTX binding as a consequence of electrical stimulation is due to a partial suppression in receptor synthesis rather than an inactivation of existing AChR, or an increase in the rate of their turnover.

Walker and Wilson¹⁴ have reported that the electrical stimulation of cultured muscle cells caused a 30-90% decrease in acetylcholinesterase (AChE) activity. Although we used the same technique for measuring the enzyme activity, our results differed considerably; in our case the decrease in AChR after electrical stimulation was accompanied by no significant change in AChE activity. Since cell injury might be the cause of the decreased AChE activity,

Fig. 2 Kinetics of ^{125}I - α -BuTX binding after saturation of AChR with cold toxin. The appearance of new receptors in 9-d-old muscle cultures was followed with labelled α -BuTX during treatment with electrical stimulation (\square), or TTX (Δ).

we monitored possible cell damage in our experiments by measuring the activity of creatine phosphokinase (CPK), which was established as an indicator for myotube proteins¹². In the experimental conditions which we chose, the electrical stimulation caused no change in CPK activity, nor was any cell damage observed (such damage was observed if the stimulation was given at a much higher frequency). Furthermore, since total protein synthesis and nucleic acid synthesis in stimulated cultures were similar to those in controls, we assume that the effect of electrical stimulation on synthesis was not a general one, but specifically affected the receptor synthesis machinery.

In conclusion, muscle fibres differentiated *in vitro* in the absence of nervous tissue have been used as a model system for the study of molecular mechanism accompanying denervation and reinnervation without the effect of a neurotrophic factor. While inactivity, like denervation, induced receptor synthesis, mechanical activity suppressed it. These results do not exclude some additional trophic influence of nerve on the muscle along with the effect of muscle usage. The existence of such an additional neurotrophic effect has recently received further support^{16,17}.

Effect of guanine alkylation on mispairing

ALKYLATING agents, such as nitrosamines, nitrosoureas, dimethylsulphate, and so on, are known to cause mutations and cancerous growth¹⁻³. Since nitrosamines can be produced by the reaction of amines and nitrous acid, the presence of nitrites and nitrous acid in many food items as well as in the urban environment has become a source of concern^{4,5}. Recent evidence⁶ has indicated that carcinogenesis and mutagenesis bear a strong relationship to each other, although agreement is not unanimous⁷. *In vivo* alkylation of DNA occurs mainly at the N7 position of guanine (G)¹⁻³. Minor alkylation of G at the O6 and N3 positions is also known to occur⁸⁻⁹. Whether alkylation at any one of these sites is mainly responsible for mutagenesis and carcinogenesis is still an open question, although O6 alkylation seems to be favoured^{8,9-11}. We have investigated the effect of methylation at each of these three sites on the ability of G to mispair with a thymine (or uracil), which may lead to a mutation, and the mechanism involved in such mispairing, using the CNDO/2 method of calculation. The calculations are carried out for the 9-methyl purines and 1-methyl pyrimidines to simulate the bases in the DNA helix. The details of the calculations are published elsewhere¹². The magnitudes reported are particular to the geometrical parameters used here¹³. Since we were only interested in the relative effect of various G methylations, the qualitative trends observed here are expected to hold; no attempt at a full minimisation of the geometric parameters was therefore made; (a horrendous task for molecules of such sizes).

Figure 1 shows the normal guanine-cytosine (G-C) and the

Fig. 1 G-C (a) and G-U base pairs (b).

$\Delta E_T - \Delta E_T^*$	0 (0)	1.35 (-105.33)	80.58 (-150.96)	-11.22 (-134.90)

* $\Delta E_T = (\Delta E_3 - \Delta E_2) + \Delta E_1$; $\Delta E_T^* = \Delta E_T$ for unmethylated G.

anomalous guanine-uracil (G-U) base pairs. Whereas the former base pair is stable in the present calculations by -22.64 kcalorie mol⁻¹, the latter is unstable by 20.03 kcalorie mol⁻¹. The stability of G-U can be enhanced by increasing the number of hydrogen bonds between G and U. This may be achieved by the interaction of: (a) a-G in the enol (e) form, where the H on N₁ is moved to the O6 position, with U in the keto (k) form; (b) an-U in the e form, where the H on N3 is shifted to position O4, with G(k). (We have already shown that this type of mispairing takes place in the case of 5-fluorouracil¹³, a known mutagen); (c) an ionised G, in which the H on N1 is removed, with U(k). This mechanism was proposed by Lawley and Brookes¹⁴, who found a large increase in the extent of such ionisation on alkylation at the N7 position. Mechanisms a and b follow the original explanation for mispairing proposed by Watson and Crick¹⁵.

In mechanism a one must estimate the energies for each of the three equations:

where MG⁺ indicates a methylated G cation. We will now denote the specific site of alkylation by a subscript to M. Table 1 shows that the e form is favoured over the k form only in the case of M₃G⁺, and that alkylation of the N3 position is the only one that leads to a greater probability for mispairing by this mechanism than G itself.

Mechanism b is very improbable due to the very low probability of finding a U in the e form¹⁶. Nevertheless, our calculations for the competitive interaction of a G(or MG⁺) with a C(k) compared with a U(e), predict that most mispairing would occur in the case of the unalkylated G. This mechanism therefore cannot explain the increase in mutation on alkylation.

In mechanism c one must compare the energies for the following steps involving the various purine species.

These energy values are shown in brackets in Table 1. The ΔE_1 values are obtained as the difference between the energies of MG(k) and MG⁺(k) for the methylated species and of G-(k) and G(k) for the unalkylated G. To obtain reliable estimates of the overall energy change in solution for step 1, one must tackle the difficult problem of solvent interaction^{16,17} with each of the purine species as well as with the H⁺ involved in the ionisation of the purines. Nevertheless, the predicted qualitative trend of an increase in ionisation on alkylation at N7 is consistent with experimental observation¹⁴. The relative differences between the ΔE_1 values for the methylated species should still

hold upon inclusion of solvent effects because of the expectedly quite close MG⁺-solvent interaction energies of the three methylated cations. Note that the greatest extent of ionisation is predicted for M₆G⁺, and that on losing the proton it is the only species that prefers to pair with a U(k) rather than a C(k), reflected in its negative ($\Delta E_3 - \Delta E_2$) value. The total relative energies in the last row of Table 1 shows that all three types of methylation increased the extent of mispairing by this mechanism in the order: M₆G⁺ > M₂G⁺ > M₇G⁺.

The results of mechanism c are consistent with the experimental ones of Gerchman and Ludlum¹¹. These authors found that O6 methylated G mispairs to U much more than N7 methylated G or G itself; and that this greater extent of mispairing was unaffected by the presence of C as a competitor.

Our results predict that methylation at the O6 and N3 positions is more effective than at the N7 position in leading to mispaired bases and therefore to mutations and possible cancerous growth. Whereas mispairing occurs by mechanism c for O6- and N7-methylated G, for N3 methylated G it may occur by either or both mechanisms a and c. The relative importance of these two mechanisms must await experiments on the relative extent of ionisation compared with enol formation for M₃G⁺.

Our calculations indicate that methylation at the O6, N7 and N3 positions of G increases the stability of the G-C base pair by -3.80, -5.22 and -11.54 kcalorie mol⁻¹, respectively. If all other interactions within the DNA helix remain unaffected (a most unlikely situation) the methylation of G while in the helical structure would therefore help stabilise the helix against denaturation. The resulting reduction in DNA replication may be responsible for the somewhat weak chemotherapeutic action of monoalkylating agents¹⁸.

Interferon, double-stranded RNA and mRNA degradation

INTERFERONS are glycoproteins which are synthesised in various animal cells following viral infection. They are excreted, interact with other cells and inhibit in them the replication of a broad range of viruses¹. Extracts from interferon-treated Ehrlich ascites tumour cells (S30_{INT}) differ in various biochemical characteristics from extracts from control cells (S30_C) (refs 2-4 and see also refs 5-8). We have reported recently that reovirus messenger RNAs (mRNAs) are degraded faster in reaction mixtures containing S30_{INT} than in those containing S30_C, but only if the reaction mixtures are supplemented with double-stranded (ds) RNA⁹. We have also reported¹⁰ that dsRNA promotes the phos-

Fig. 1 The preparation of $S30_C$, $S30_{INT}$, reovirus dsRNA, 3H -labelled reovirus mRNA (enriched in medium size class mRNAs) and the procedures for the reovirus mRNA degradation assay have been described before⁹. The reaction mixtures included $30 A_{260} ml^{-1}$ of $S30$ which had been passed through Sephadex G-25, $5 \mu g ml^{-1}$ of reovirus dsRNA, $50 \mu g ml^{-1}$ of 3H -labelled reovirus mRNA as well as all the components of an *in vitro* protein synthesising system⁹, with the following omissions: *a*, amino acids, *b*, amino acids and all the energy source (namely, ATP, GTP, CTP, phosphoenolpyruvate, creatine phosphate, creatine kinase); *c*, amino acids and all the energy source except ATP. The reaction mixtures were incubated at $30^\circ C$ for 30 min. The reactions were terminated by the addition of buffer A (0.1 M NaCl, 10 mM Tris-Cl (pH 7.5), 1 mM EDTA) containing 0.5% SDS. Proteins were removed by extraction with equal volumes of phenol. The aqueous layers (containing RNA) were layered on 12.5-ml linear sucrose gradients (7–25% w/v) in buffer A. The gradients were centrifuged at $2^\circ C$ at 39,000 r.p.m. for 12 h in the SB283 rotor in an IEC B60 ultracentrifuge. Fractions were collected and the radioactivity in each was determined. Δ , Unincubated reaction mixture with $S30_{INT}$; \bullet , reaction mixture with $S30_C$; \circ , reaction mixture with $S30_{INT}$.

phorylation by ATP of at least two proteins in $S30_{INT}$. Here we describe further characteristics of the faster degradation of reovirus mRNA in $S30_{INT}$ supplemented with dsRNA. ATP is required, in addition to dsRNA, for the acceleration of mRNA degradation in $S30_{INT}$ (ref. 11), and we show that this phenomenon can be divided into two phases. In the first phase (activation) both dsRNA and ATP, but not reovirus mRNA, are required; in the second phase (endonuclease action), in which added reovirus mRNA is degraded, it seems that neither dsRNA nor ATP has to be present.

Previously we have observed the faster degradation of reovirus mRNA in the presence of dsRNA in reaction mixtures containing $S30_{INT}$ as well as all components used for *in vitro* protein synthesis^{9,10}. As Fig. 1*a* shows, faster degradation is also manifested in a reaction mixture not supplemented with amino acids. It is not manifested when neither amino acids nor the energy source is present in the reaction mixture (Fig. 1*b*), but it is manifested when ATP is added (Fig. 1*c*). The commercially available ATP can be replaced by a further purified ATP preparation containing less than 0.1% ADP as the only impurity detected by chromatography and ultraviolet absorption.

The existence of two phases in the phenomenon of faster reovirus mRNA degradation in $S30_{INT}$ is revealed in the experiments shown in Figs 2 and 3. The addition to the reaction mixture of the various components, namely dsRNA, ATP, RNase III (an enzyme hydrolysing dsRNA, but not single-stranded RNA)^{12,13}, glucose and hexokinase (transforming ATP to ADP), and reovirus mRNA, was staggered in these experiments. The results in Fig. 2*a* and *b*

verify that dsRNA is required, in addition to ATP, for the faster mRNA degradation. The faster mRNA degradation is also manifested when both ATP and dsRNA are added at 0 min but dsRNA is degraded after 5 min by the addition of RNase III (Fig. 2*c*). To prove that an RNase III-treated dsRNA cannot activate $S30_{INT}$ for faster mRNA degradation it is shown that there is no enhanced mRNA degradation: (1) if dsRNA and RNase III are added simultaneously at 0 min and ATP as well as reovirus mRNA are added later (Fig. 2*d*), or (2) if dsRNA, RNase III and ATP are added together at 0 min and reovirus mRNA is added later (data not shown). These results do not rule out the possibility that segments of dsRNA might attach to protein during the 5-min incubation (in the absence of RNase III) and thus be protected from hydrolysis by RNase III added later.

The results in Fig. 3*a* and *b* verify that ATP is required, in addition to dsRNA for the faster reovirus mRNA degradation. The activated state persists even after ATP is removed by the addition of hexokinase and glucose (Fig. 3*c*). Hexokinase and glucose are effective in removing ATP since no activated state is reached if ATP, hexokinase and glucose are added simultaneously at 0 min and dsRNA and reovirus are added later (Fig. 3*d*). We have also established that a reaction mixture, which has been incubated with dsRNA and ATP (from 0 min), retains its activated state even if dsRNA is hydrolysed (by RNase III added at 5 min) and ATP is removed (by hexokinase and glucose added at 5 min) (data not shown).

These results indicate that dsRNA and ATP are needed in the activation phase but seem not to be needed in the

endonuclease action phase. The role (if any) of the dsRNA and ATP-promoted protein phosphorylation in S30_{INT} (ref. 10) in the process of activation is under investigation. It remains to be seen whether the faster degradation of reovirus mRNA in S30_{INT} is a result of increased endonuclease activity or of increased susceptibility of the reovirus mRNA to endonuclease action. An increased susceptibility of the mRNA may arise if dsRNA diminishes ribosome binding to mRNA and polysome formation more in S30_{INT} than in S30₀ (ref. 6). The hypothesis of increased mRNA susceptibility as the basis of the phenomenon is made unlikely by the finding that the protein synthesis inhibitors (sparsomycin and edeine) do not diminish the difference between S30_{INT} and S30₀ in the rate of reovirus mRNA degradation in the presence of dsRNA (to be published). The addition of dsRNA and ATP to S30_{INT} affects the rate of degradation of some RNAs much more than that of others. It accelerates the degradation of reovirus mRNAs from the large size class much more than that of those from the medium or small size classes. Furthermore, it increases the rate of degradation of an unfractionated mRNA preparation from Ehrlich ascites tumour cells much more than that of either Ehrlich ascites tumour cell ribosomal RNA or mouse globin mRNA (to be published). It may be relevant to note that

Fig. 2 The reaction mixtures included all the components as described for Fig. 1b except that 33 $\mu\text{g ml}^{-1}$ of reovirus mRNA was added only after 35 min incubation and all reactions were performed with S30_{INT} only. ATP (1 mM), reovirus dsRNA (2 $\mu\text{g ml}^{-1}$) and 25 U ml^{-1} of RNase III (a gift from Dr R. Crouch) were added as indicated at the times specified. The reaction mixtures were incubated at 30 °C for a total of 50 min. *a*, -dsRNA + ATP (0 min); *b*, + dsRNA (0 min) + ATP (0 min); *c*, + dsRNA (0 min) + ATP (0 min) + RNase III (5 min); *d*, + dsRNA (0 min) + RNase III (0 min) + ATP (30 min).

Fig. 3 The conditions were similar to Fig. 2 except that 10 mM glucose and 10 U ml^{-1} of hexokinase (Sigma) were added in *c* and *d* at 5 and 0 min, respectively. It was shown in control experiments that 10 mM glucose, or 10 U ml^{-1} of hexokinase, or 1 mM glucose-6-phosphate added individually at 0 min (together with dsRNA and ATP) did not impair the activation of the reaction mixture for faster mRNA degradation (data not shown). *a*, + dsRNA (0 min) -ATP; *b*, +dsRNA (0 min) +ATP (0 min); *c*, +dsRNA (0 min) + ATP (0 min) + glucose and hexokinase (5 min); *d*, + ATP (0 min) + glucose and hexokinase (0 min) + dsRNA (30 min).

viral RNA accumulation has been reported to be impaired in interferon-treated cells infected with different viruses¹⁴⁻¹⁷.

- the physical state of the substrate. The enzyme from snake venom is highly active when the substrate is tightly packed in a membrane. Mammalian phospholipases cannot attack membranes; they can degrade the lecithin molecules most effectively when these are more loosely packed in micelles. All phospholipases also have some activity towards substrates in a monomeric solution. The precursors from mammalian pancreas phospholipases are also active towards the monomeric substrate molecules, but inactive to substrates in micellar form⁶. The primary structure of many of the phospholipases A₂ is known. They have a single polypeptide chain of approximately 130 amino acid residues and six or seven disulphide bridges⁷⁻¹⁰. There is a high degree of homology between all the enzymes. We report here the three-dimensional structure of one of these enzymes, prephospholipase A₂ from porcine pancreas.

Crystallisation was accomplished as follows. The enzyme was dissolved in a 0.05 M Tris-maleate buffer, pH 7.2, with 5 mM CaCl_2 . To 50 μl of this solution was added 10–15 μl of methanol. After 1 week crystals had grown to sizes up to $0.5 \times 0.5 \times 0.5$ mm. The space group of the crystal form was $P3_121$ with $a=b=69.8$ Å and $c=67.6$ Å. There was one molecule in the asymmetric unit and the solvent content

of the crystals was 62%. For structure determination we used one heavy atom derivative— $K_3UO_2F_6$ —with the anomalous scattering data of the uranyl atom (the SIRAS method). An electron density map was calculated to a resolution of 3 Å. This map—though of mediocre quality—could be interpreted easily with the aid of the known amino acid sequence⁷.

The polypeptide chain in the prephospholipase A_2 molecule consists of 132 amino acid residues, 14 of them involved in disulphide bridges. These seven bridges provide an internal check on the correctness of the interpretation of the electron density map, because the polypeptide chain always has to return to a bridge at a known position in the amino acid sequence.

The molecule has the shape of a rectangular box, with dimensions of approximately $25 \times 28 \times 35$ Å (Fig. 2). It contains neither regular α helices nor β -pleated sheets; only two parts are in a distorted helix conformation—residues 11–17 and 36–41. Four disulphide bridges are more or less in a plane through the middle of the molecule and three are at the surface. The N-terminal heptapeptide in prephospholipase has the sequence Glu–Glu–Gly–Ile–Ser–Ser–Arg. It shows up as a bent tail at the molecular surface. During the activation of prephospholipase by the action of trypsin the peptide bond Arg 7–Ala 8 is split. This bond is in an exposed position on the surface of the molecule.

His 55 is part of the active site of porcine (pre-)phospholipase A_2 (ref. 11). Incorporation studies, using ^{14}C -labelled *p*-bromophenacyl bromide showed that loss of enzyme activity was accompanied by the incorporation of 1.1 ^{14}C -*p*-bromophenacyl residues and by the loss of 1 histidyl residue per mol of protein. Divalent metal ions (Ca and Ba), however, protect the enzyme against this inactivation. In the electron density map, we find in the neighbourhood of His 55 a peak of density that can be interpreted as a Ca ion. It is close to the side chains of Asp 107 and Asn 57. Ca ions are also an absolute requirement for crystallisation. The crystals crack when the Ca ions are removed by addition of EDTA. When calcium binds to the protein, the spectrum in the ultraviolet region changes¹². The difference spectrum shows a perturbation of one or more tyrosine and histidine residues. One tyrosine residue, Tyr 35, is close to His 55 and the Ca-binding site (Fig. 3).

The molecular model suggests a binding mode for monomers of the substrate. It is reasonable to assume that the phosphate moiety of the substrate is bound to Arg 108 and the Ca ion. This would be similar to staphylococcal nuclease where the 5'-phosphate group of the substrate is bound specifically to the enzyme by two guanidino groups with the Ca ion 4 Å from the nearest phosphate oxygen atom¹³. In phospholipase A_2 Arg 108 is always present, except for notexin¹⁰, but the catalytic action for the latter enzyme seems to be different. The carbonyl oxygen of the ester bond to be split could well point towards the imidazole ring of His 55. Then the hydrophobic part of the lecithin molecule could fold along a highly hydrophobic surface part of the enzyme. This surface part consists of the side chains Leu 48, Cys 51–Cys 106, Thr 54, Ile 103, Phe 102 and Cys 69–Cys 99.

To predict a mechanism for the esterase activity of phospholipase we made a comparison with other ester splitting enzymes. It is well known that proteolytic enzymes have esterase as well as proteolytic activity and that the mechanism for splitting an ester bond is essentially the same as for splitting a peptide bond. X-ray crystallographic analysis of several proteolytic enzymes has provided a picture of the catalytic process in the active site.

The catalytic action of the serine enzymes starts with nucleophilic attack of the serine OH on the carbonyl carbon of the substrate^{14,15}. A tetrahedral intermediate, which has a negative charge on its carbonyl oxygen, is formed. The

Table 1 Functional groups in esterases

Enzyme	Nucleophile	Proton donor	Stabiliser
Serine enzymes	Ser OH	Imidazole H ⁺	Amide NHs
Papain	Cys S ⁻	Imidazole H ⁺	Amide NHs
Carboxypeptidase	COO ⁻ (+H ₂ O)	Tyr OH	Zinc
Thermolysin	COO ⁻ (+H ₂ O)	Imidazole H ⁺	Zinc
Phospholipase A_2	COO ⁻ (+H ₂ O)	Tyr OH	Imidazole H ⁺

tetrahedral intermediate is stabilised by amide NH groups in the active site wall. The splitting of the peptide or ester bond is accompanied by a protonation of the leaving group at the peptide NH or the ester oxygen atom. The proton donating group in the serine enzymes is the imidazole ring next to the serine, transferring a proton from the serine to the leaving group. As a result of this process the enzyme is acylated. Deacylation proceeds through similar steps, water replacing the leaving group. Thus three functions have a key role in the catalytic mechanism of the serine enzymes (Table 1): (1) the serine OH as a nucleophile; (2) the amide NH groups as stabilisers for the tetrahedral intermediate; and (3) proton donating imidazole.

From an X-ray study of papain derivatives a reasonably reliable picture has been obtained for the catalytic mechanism of this sulphhydryl protease¹⁶. It turned out to be very similar to the action of the serine enzymes. The sulphhydryl group is the nucleophile. The side chain NH₂ of Gln 19 and the main chain NH of Cys 25 contribute to the stabilising function. The imidazole ring of His 159 gives up a proton to the leaving group.

The proteolytic zinc-dependent enzymes, carboxypeptidase A_1 ¹⁷ and thermolysin¹⁸, both use the zinc ion as the stabiliser for the carbonyl oxygen. They also have the same nucleophile, which is either the carboxyl group of a Glu residue or a water molecule with its nucleophilicity increased by these carboxyl groups. The proton donating group is different for these two enzymes, being Tyr in carboxypeptidase A_1 and His in thermolysin.

A similar set of three important functional groups should be present in other enzymes with a proteolytic or ester splitting activity. In this way we could assign functions to some side chains in the active site of phospholipase A_2 . Searching for the three functions mentioned above we find Asp 56, His 55 and Tyr 35. These residues are conserved in all other phospholipases sequenced. The position of the three residues in the molecular model suggests that the Asp is the nucleophile, the imidazole ring the stabiliser and that Tyr has a proton donating function. These predictions for phospholipase A_2 should be verified, for example, by crystallographic binding studies and specific chemical modifications.

All phospholipases A_2 with known amino acid sequence show a striking homology, especially for those parts of the polypeptide chain which are in the active site region. His 55, Tyr 35, Asp 56 and Asp 107 are absolutely conserved: the conservative part 32–37 has two cysteines in S–S bridges with the main chain atoms of Tyr 35 fixed in between. The hydrophobic region shows a functional homology: only Cys 51–Cys 106 is the same in all enzymes; for the other parts a high degree of hydrophobicity is maintained, but not necessarily by identical residues. When, for example, Phe 102 is replaced by a serine residue, threonine at position 54 is always replaced by isoleucine. The most variable parts of the sequence are located on the surface of the molecule, away from the active site region.

The high activity of active phospholipase A_2 towards the micellar substrate cannot yet be explained.

We thank Professor De Haas for the protein material and Mrs G. Drent for technical assistance. We thank Drs M.

Pierrot and H. Reynaers for crystallising the enzyme. This work was supported in part by the Netherlands Foundation for Chemical Research with financial aid from the Netherlands Organisation for the Advancement of Pure Research

Organisation of the polypeptide chains in mammalian keratin

THE keratins are insoluble intracellular α -fibrous proteins which represent the major structural proteins of epidermis. X-ray diffraction studies of keratins in the early 1950s^{1,2} yielded a pattern since shown to be typical of intact epidermal tissue and epidermal α keratins. This pattern, which consists of a meridional arc at 5.15 Å and an equatorial reflection at 9.8 Å, was suggested to be indicative of polypeptide chains packed in a partially α -helical coiled coil configuration. Crick³ suggested that a three-stranded model was appropriate for α keratins, and although two-stranded and seven-stranded models have also been proposed, the triple α -helical coiled coil configuration has been a dominant concept in keratin structure⁴. Rudall made the initial contribution of epidermal keratin chemistry by using urea buffers to extract and characterise the α -fibrous proteins from cow snout epidermis. Matolsky subsequently showed that an α -fibrous protein, which he designated prekeratin, could also be isolated by extraction with citrate buffer, pH 2.65, and purified by isoelectric precipitation. His data indicated that the prekeratin was an α -helical, rod-like molecule with a molecular weight of 640,000 (ref. 5). Detailed studies^{6–8} have shown that epidermal keratins consist of several different polypeptide chains, and we describe here experiments which suggest how these chains may be organised in the native keratin molecule.

Prekeratin, the epidermal keratin, was prepared according to Matolsky⁵, and the sodium dodecyl sulphate (SDS)-polyacrylamide electrophoretic pattern obtained using the discontinuous system of Neville⁹ is shown in Fig. 1. The relative proportions of each of the bands were determined by scanning the gel to measure the amounts of Coomassie blue dye bound to each chain. After taking into account that the amount of dye binding is proportional to the molecular weights of the chains, it can be shown that the three major

Fig. 1 SDS-polyacrylamide electrophoresis of keratin from cow snout epidermis. The gels are 7% acrylamide 2% bisacrylamide and run at pH 9.5 using the discontinuous gel system described by Neville⁹. Gels were run at 2 m per gel for 2 h at 25 °C and fixed and stained with Coomassie blue in 7.5% acetic acid (v/v) and 5% methanol (v/v). The direction of migration is downward. Samples were equilibrated in 8 M urea, 1% SDS and 1% mercaptoethanol for 1 h at 50 °C and dialysed against 1,000 volumes of upper gel buffer before loading on gels.

bands, designated B, A, A', are present in approximately equal amounts. A fourth component B' is also present but in much smaller amounts than B, A or A'. Having isolated the major polypeptide chains of keratin on DEAE cellulose as previously described¹⁰, we could perform X-ray diffraction studies on fibres pulled from solutions of purified chains and from solutions in which the chains had been recombined in the ratios shown in Table 1. Experimental detail is given

Table 1 X-ray diffraction patterns

Sample	Presence of a pattern
Prekeratin	Yes
A	No
B	No
A + A'	No
B + B'	No
A + B	No
2A + B	Yes
A + A' + B	Yes
2A' + B	Not done

Fibres (between 1 and 2 cm long) from the above solutions were prepared for X-ray diffraction in one of three ways: (1), lyophilised protein was dissolved in 80% formic acid and the gelatinous mixture was taken up and stretched between the tips of forceps; (2) solutions of protein in 0.1 M citric acid were dialysed against 0.1 M NH_4HCO_3 , pH 9.0 and the filaments that formed were picked up and stretched between forceps; (3) solutions of protein dissolved in 8 M urea containing 0.01 M Tris at pH 8.5 were dialysed against water and the filaments that formed were also picked up and stretched between forceps. The protein content of solutions of purified chains was measured by the Lowry technique before they were combined in the molar ratios shown. Fibres were mounted with a specimen-to-film distance of 1.54 cm and exposed to $\text{CuK}\alpha$ radiation ($\lambda = 1.54 \text{ Å}$) at 40 kV. Finely powdered KCl was dusted on to selected fibres before exposure and the 2.224 Å spacing was used for calibration purposes. Variations of measurements from replicate fibres was less than 0.1 Å. The presence of an α pattern was indicated by a sharp meridional arc at $5.15 \pm 0.1 \text{ Å}$ and an equatorial reflection at $9.8 \pm 0.1 \text{ Å}$.

in the legend. Purified *A* and *B* chains alone did not produce an X-ray diffraction pattern typical of α -fibrous proteins; however when these chains were combined in a ratio of 2:1 (*A* to *B*) an α X-ray pattern indistinguishable from that of either intact keratin or epidermis was obtained. This is interesting in the light of our previous descriptions of these chains which showed that *A* and *A'* and *B* and *B'* were chemically and immunologically related to one another and formed two distinct families (*A* and *B*) of polypeptide chains associated with keratins¹⁰.

Although these studies supported an unlike-chain (*AA'B* or *AA'B'*) hypothesis for the assembly of the keratin molecule, it seemed possible that a series of keratins composed only of the identical individual peptide chains (*AAA*, *A'A'A'*, *BBB* or *B'B'B'*) might exist. In the unlike-chain arrangement each of the three principal chains (*AA'B*) would be packed in a triple α -helical arrangement with a monomer molecular weight of 159,000. This unit could form dimers (molecular weight 318,000) or tetramers (molecular weight 636,000). The minor component *B'* could also form intact keratin molecules *AA'B'*, with a monomer molecular weight of 153,000 which would be present in smaller amounts and constitute a variant form. Such variant forms have been shown to exist for other structural proteins such as collagen¹¹ and fibrinogen¹².

On the other hand, if identical chains combined with themselves the following species would exist in solution: *AAA* (monomer molecular weight 135,000; dimer, 270,000); *A'A'A'* (monomer, 144,000; dimer, 288,000); *B'B'B'* (monomer, 180,000; dimer, 360,000) and *BBB* (monomer, 201,000; dimer, 402,000). It is possible that in the intact keratin molecule these species are the fundamental units from which the molecule is built.

Intact keratin molecules predicted from the unlike-chain and identical-chain hypotheses would give distinctly different SDS electrophoretic distributions as shown in Fig. 2, providing their interchain associations were not disrupted. Disruption of interchain associations was prevented by chemically crosslinking the polypeptide chains of the keratin molecule with formaldehyde using the techniques of Veiss and Drake¹³ and Nold and Cross¹⁴ for crosslinking collagen. The densitometer tracing of SDS electrophoretic patterns of crosslinked prekeratin (Fig. 3) is clearly similar to that of

Fig. 2 Predicted densitometer tracings of the SDS-polyacrylamide electrophoretic patterns of formaldehyde-crosslinked keratin. Solid line, multichain lymphoreis; broken line, single-chain hypothesis.

Fig. 3 The solid line represents the densitometer tracing of the SDS-polyacrylamide pattern of formaldehyde-crosslinked prekeratin and the dotted line the theoretical curve for a multichain structure. The amounts of formaldehyde were varied from 1.5 to 6.2% and the times of reaction were varied from 1 h to 3 d to obtain conditions which crosslinked all the available polypeptide chains of keratin but did not yield polymers too heavy to penetrate 5% polyacrylamide gels. The optimal conditions used in all crosslinking experiments reported were as follows. Prekeratin dissolved in 0.1 M acetic acid (1 mg ml⁻¹) was incubated with formaldehyde at a final concentration of 6.2% for 4 h at 4 °C, conditions which were shown not to crosslink solutions of single chain control proteins. After exhaustive dialysis against 0.1 N acetic acid, samples were equilibrated and run as described in Fig. 1, except that 5% acrylamide gels were used. The following molecular weight markers were used: BSA monomer (67,000) and dimer (134,000); phosphorylase A (94,000); λ globulin (150,000).

the predicted unlike-chain molecule comprised of an *A*, *A'* and *B* chain. The variant molecule (comprised of *A*, *A'* and *B'*) is too close in molecular weight to the major species to be seen as a separate peak. The molecular weights obtained for the monomer (144,000) and dimer (280,000) are approximately 10% lower than the theoretical values, which is expected as the crosslinked keratin molecules are not fully accessible to SDS. This may well be analogous to the situation with other proteins such as bovine serum albumin (BSA)¹⁵ where the folded molecule (unreduced) has a lower apparent molecular weight than the unfolded (reduced) species on SDS gels.

Our data indicate that the basic building block of the keratin molecule is composed of two *A* chains and one *B* chain. Skerrow's work¹⁷ in which he isolated a highly helical core, after tryptic digestion of keratin, which consisted of three distinct polypeptide chains, seems to support this concept. It is thought that this basic unit can readily polymerize to form the higher molecular weight units initially reported by Matoksy and is presumably the fundamental unit of the tonofilaments seen *in vivo*.

We thank Dr Ervin H. Epstein Jr for helpful suggestions.

'Sandwiched' water molecule between pyrimidine bases and intra-molecular C-H...O hydrogen bonding in 5-nitro-1-(β -D-ribose)uracil monohydrate

IN the structure of crystalline 5-nitro-1-(β -D-ribose)uracil monohydrate we have found a novel disposition of a water molecule—'sandwiched' between two parallel pyrimidine rings stacked 6.55 Å apart. The water molecule is held in its place between these rings by a short O-H...OW (2.589 Å) hydrogen bond from the carboxyl group of a uronic acid molecule belonging to an adjacent stack. We have also found that nitro groups adjacent to C-H bonds in the heterocyclic ring of nucleic acid bases apparently polarise these bonds and cause them to take part in strong hydrogen bonds to appropriate donors. The polarisation effect of the nitro group adjacent to the C-H bonds in pyrimidine is perhaps analogous to that of a positive charge adjacent to the C-H bonds in purines¹.

We have been studying the structures of a series of nitro derivatives of nucleic acid bases and nucleosides in connection with a study of radiation damage and sensitisation. To this end, we prepared crystals of 5-nitro-1-(β -D-ribose)uracil monohydrate by treating uridine with dilute nitric acid², and then slowly evaporating the resulting solution. The crystals so obtained (of $C_9H_9N_3O_9 \cdot H_2O$) are monoclinic, space group $P2_1$, with cell dimensions (at $22 \pm 3^\circ C$): $a = 8.982(1)$, $b = 10.245(1)$, $c = 6.651(1)$ Å, $\beta = 92.27(1)^\circ$, with a density of 1.74 g cm^{-3} (calculated density = 1.743 g cm^{-3}) (this is higher than usually observed for nucleosides). The crystal structure was determined from the intensities of $CuK\alpha$ X-ray 'reflections' measured by a diffractometer out to $2\theta = 165^\circ$. Multi solution³ and trial and error methods were used, and the parameters were refined by the least-squares method, in the block-diagonal approximation, to a final

Fig. 1 Structure and conformation of the molecule. Note the internal C-H...O hydrogen bonding.

Fig. 2 The 'sandwiching' of water molecules between nucleic acid bases, as seen edgewise. The water molecule here acts as a 'spacer' keeping the bases 6.55 Å apart. The 5-nitro group has been omitted in this figure for clarity.

discrepancy factor of 0.056 for the 1,427 reflections with values of I greater than 2σ . All the hydrogen atoms, except the pair on the water molecule, were located from electron-density difference maps and their parameters were refined using individual isotropic thermal parameters.

The molecular structure and conformation are displayed in Fig. 1. The pyrimidine ring is slightly non-planar with N(1) and C(4) deviating from the least-squares plane through the other four atoms by 0.037 and 0.022 Å, respectively. The nitro group is slightly twisted away from the plane of the uracil ring; the C(4)-C(5)-N(5)-O(5b) torsion angle is 7.6° . The molecule is in the *anti* conformation ($\chi_{CN} = 53.9^\circ$), if we may extend the nomenclature for nucleosides⁴ to this molecule. The furanose ring has the C(2')-*endo*-C(3')-*exo*(²T₂) conformation, with C(2') and C(3') deviating from the plane of the other three atoms by 0.418 and -0.199 Å, respectively. The pseudorotation parameters⁵ for the five-membered ring are $P = 171^\circ$ and $\tau_m = 38^\circ$. The torsion angles O(1')-C(4')-C(5')-O(5') and C(3')-C(4')-C(5')-O(5') which describe the relative orientation of the hydroxyl with respect to O(1') and C(3') are -20.4° and 98.3° , respectively. Similar conformation of a β -D-uronic acid has been observed⁶ in thymidine 5'-carboxylic acid. In the usual nucleoside nomenclature, this conformation may be referred to as *gauche*⁺ (*g*⁺, or *gg*). But the conformational preferences of the CH₂OH and COOH groups are different and the torsion angles

Fig. 3 Partial overlap of the nucleic acid bases and the water in between, viewed normal to the plane of the uracil ring.

are quite different from $\pm 60^\circ$. A more appropriate notation for describing this conformation may be that of Klyne and Prelog⁷; O(5') is (–) *syn*-periplanar to O(1') and (+) *anti*-clinal to C(3').

The *anti* conformation of this molecule is stabilised by an internal C(6)–H(C6) ... O(5') hydrogen bond of length 3.104 Å (Fig. 1). The role of C–H ... O (ref 8) in conferring some stability to the *anti* conformation of nucleosides and nucleotides has been pointed out by several workers^{9–11}. It is known from deuterium exchange experiments¹² and proton magnetic resonance studies¹³ in solution that the hydrogen on C(8) of purines and C(6) of pyrimidines is acidic. Our results indicate that the location of an 'electron withdrawing' nitro group adjacent to C(6)–H causes additional polarisation of the C–H bond, and thus enables the hydrogen to take part in a C(6)–H(C6) ... O(5') hydrogen bond. This polarisation effect of nitro groups in pyrimidines is analogous to that of a positive charge adjacent to C–H bonds in purines¹, as discussed by us recently. Sundaralingam^{4,10} has pointed out that nucleotides are less flexible than nucleosides. A part of this additional stability in the *anti* conformation of 5'-phosphorylated nucleotides, at least for those nucleotides that can take up a zwitterionic form, is probably due to the charge on the heterocyclic ring and the polarisation of the C(6)–H or C(8)–H bonds.

An interesting feature in the present structure is the wealth of C–H ... O hydrogen bonds and weaker interactions. All carbons in the furanose ring except C(1') take part in C–H ... O contacts in which the H ... O distances and the C–H ... O angles range from 2.27 to 2.41 Å and 130° to 163° , respectively. The uracil rings are not self-paired; N(3) is hydrogen bonded to O(5') of a neighbouring molecule (N(3)–H(3) ... O(5'), 2.855 Å; H(3) ... O(5'), 2.13 Å; N(3)–H(3) ... O(5'), 168.4°).

The most remarkable feature in this structure is the location of the water molecules; they are between successive, parallel pyrimidine bases of a stack, the members of which are related by translations along *c* and are 6.55 Å apart (Fig. 2). The water molecule is 3.43 Å from the plane of the base above and 3.12 Å from the plane of the base below, thereby forming a 'sandwich' (Fig. 3). The distances are similar to base stacking distances in nucleic acid polymers and crystals of monomers. The water

molecule is held in this location by a strong but bent hydrogen bond (O(5')–H(O5') ... OW, 2.589 Å; H(O5') ... OW, 1.71 Å; O(5')–H(O5') ... OW, 128°) from the carboxyl group of a neighbouring molecule in an adjacent stack. The shortest contacts of the water molecule are with the atoms in the pyrimidine ring below and are: O(W) ... N(1), 3.229 Å; O(W) ... C(2), 3.260 Å; O(W) ... O(1'), 3.305 Å. All other contacts are longer than 3.4 Å. Since the hydrogen atoms of the water molecule cannot be located in electron density difference maps they must be disordered. Thus, it is not possible to decide whether the O(W) ... N(1) contact is a van der Waals' contact or a weak hydrogen bond, but the stereochemistry is unfavourable for the latter.

The stacking of bases does not take place in organic solvents, but does in water; this interaction between bases has been interpreted as 'hydrophobic stacking interactions'¹⁴. It is well known that several heterocyclic dyes and polycyclic hydrocarbons bind to the bases in accord with the intercalation mechanism of Lerman¹⁵. An extensive analysis of the stacking in the solid state¹⁶ indicates that the stacking pattern in a crystal is specific and the bases stack with electronegative heteroatoms forming close contacts with adjacent aromatic systems. In view of these results, the water 'sandwich' we have found is very unusual and, as far as we know, has not been observed before. It is not clear what forces are responsible for the stability of these water-intercalated nucleic acid base stacks. In any case, our results show that such an intercalation of water molecules between nucleic acid bases is possible in certain circumstances. If so, the consequences of water intercalation in nucleic acids should be extremely important and very diverse. We shall mention only one possible example of these consequences. When there is non-complementary opposition—due either to point mutation¹⁷, or to the transient, non-complementary formation of short helices, or to enzymatic excision followed by repair of strands—the non-complementary bases may swing out and assume extrahelical conformations. In such cases, a water molecule could intercalate and act as a 'spacer', giving some stability to the nucleic acid stacks. Such intercalation of water must be very rare in view of the very limited number of mistakes that occur in nucleic acid replication. On the other hand, as our crystal structure demonstrates, such intercalation of water between nucleic acid bases cannot be ruled out. Further work is necessary to discover the conditions favourable to the formation of such hydrated polymers.

We thank Dr D. Harker for discussions, the NCI for financial support and Mrs G. Hazel for technical assistance.

matters arising

Stability of Lotka-Volterra systems

IN our recent paper in this journal, we claimed that global stability was a consequence of the negative-definiteness of a matrix $B = (A + A')/2$. The subsequent argument was accurate to the extent that if B is found to be negative-definite, then the system must be locally and globally stable. Since A is taken to be an arbitrary matrix, however, it is possible that A can be stable while B is not negative-definite. This means that there may be some locally stable systems that are not globally stable.

The arguments and conclusions are therefore modified as follows. Let d_i be a set of n strictly positive numbers. Introduce the Liapunov function

$$V(x) = \sum_i 2d_i[\exp(x_i) - x_i - 1]$$

which has time derivative $dV/dt = u'(DA + A'D)u$ where u is the vector with elements $[\exp(x_i) - 1]$, and D is a matrix with diagonal elements d_i and zeros elsewhere. This allows us to state the following theorem: if there exists a strictly positive diagonal matrix D such that $(DA + A'D)$ is negative-definite, the Lotka-Volterra system is simultaneously locally and globally stable.

It is not possible to say that all locally stable states are globally stable. The criterion of the previous paragraph is in general a sufficiency condition, not a necessity condition. The criterion does identify the largest known subset of locally stable states that are also globally stable. This is the strongest result available on global stability so far.

Some interesting, if enigmatic, features are worth noting. First, setting $D = I$, the unit matrix, our theorem shows that negative-definiteness of the symmetric part of the community matrix A is sufficient to ensure local and global stability. Second, if $D = N^*$, negative-definiteness of the symmetric part of the interaction matrix α which has elements a_{ij} is also sufficient to ensure local and global stability. Third, the theorem stated above identifies a subset of the possible matrices A which is also D -stable². This means that for this subset stability depends only on the interaction matrix α and is independent of the precise value of N^* , so long as all N_i^* are strictly positive. Such an identification

is in accord with intuitive feelings about the relationship between the geometry of the isoclines of the Lotka-Volterra systems and the flow in phase space.

Finally, there is a strong connection with qualitative (or sign) stability³, which involves the analysis of interaction matrices α where only the signs of the interaction elements are known. Our theorem above shows directly that Lotka-Volterra models which have sign stable interaction matrices α with strictly negative diagonal elements have globally stable dynamics.

Since submitting this manuscript the error in our original paper has independently been pointed out to us by Dr. H. I. Freedman, Department of Mathematics, University of Alberta. In addition Drs. Granero-Portat and Zanaua, Institute of Physics, Parma questioned our use of a community matrix with elements $(a_{ij}N_j^*)$; however we pointed out that such matrix has the same eigen values as a matrix with elements $(N_i^*a_{ij})$.

Relatedness

ALTHOUGH the article by Dawkins and Carlisle¹ points out relevant questions regarding desertion, it also perpetuates a misconception concerning relatedness. In their example, a female with enough food to support only one infant must choose between two infants the same age, an orphaned baby brother and her own son. They conclude "Intuition points to the son but this is not necessarily correct. There are no genetic grounds for preferring either infant: the mother's relatedness to both is the same, 0.5." There is, however, a genetic difference! The degree of relatedness between two siblings is only on the average 0.5, in any particular instance it may be much less or much greater than that. Additional assumptions are required to state that behaviour is based on average relatedness. Although it could hardly be considered to prove anything, the intuitive

response to save the offspring might, in fact, indicate that nature prefers a sure thing (relatedness=0.5 as in the case of the son) to gambling (average relatedness=0.5 as in the case of the siblings). In addition, in the example they used, even the average relatedness was $\neq 0.5$. Assuming a dioecious diploid organism whose parents are not related, opposite sexed siblings are actually somewhat <50% related on average since they must necessarily have one sex determining chromosome which is not in common. Similarly, siblings of the same sex are on average somewhat >50% related.

It should be noted that the validity of their conclusions is not affected by this correction.

¹ Dawkins, R., and Carlisle, T. R., *Nature*, **262**, 131-133 (1976).

DAWKINS REPLIES—Gibson¹ is right, both in the main point she makes and in her observation that it doesn't matter anyway. But her gambling analogy is misleading.

She thinks of the offspring as a safe bet while the sibling is a risky gamble. Yes, setting aside Gibson's trivial point about sex chromosomes, it is true that exactly 50% of the genome of a parent is inherited by a given child, while siblings share 50% of their genomes only on average. But who cares about genomes? Certainly not natural selection, at least in sexual populations². From the point of view of a single altruistic gene sitting in the body of an individual, a particular child of that individual is just as risky a prospect as a particular sibling. The gene may or may not be present in the body of the offspring, and it may or may not be present in the body of the sibling. It is a 50% gamble in both cases.

Fast axonal transport and amine levels

THE monoamine oxidase inhibitor, pargyline, which raises amine levels, produces a myopathy which can be prevented by previous nerve section¹. The fact that the pargyline-induced myopathy could be prevented by nerve section led Boegman and collaborators to look at effects of this drug on axonal transport. They reported that pargyline treatment caused a dramatic increase in the velocity of axonal transport², and so I decided to see what effects the reported increased velocity of transport might have on life span or composition of transported protein.

Male Sprague-Dawley rats (250–300 g) were injected intraperitoneally with the following solutions: (1) 1 ml saline for 3 d before the experiment (controls); (2) 25 mg kg⁻¹ pargyline (Parsidol, Abbott Pharmaceuticals) in 1 ml saline for 3 d; (3) 75 mg kg⁻¹ pargyline for 3 d, (4) 2.5 mg kg⁻¹ reserpine (Serpasil, Ciba) for 7 d. Injection of ³H-L-leucine into the ventral horn of the lumbosacral cord was performed as described previously¹. At intervals after injection of precursor, the sciatic nerve and ventral roots were dissected out, cut into segments, and placed in 10% TCA overnight. TCA-insoluble material was dissolved in Protosol (New England Nuclear) and counted. In a few experiments TCA-soluble activity was counted by adding Scintiverse (Fisher). In some animals whole brain, right atrium and soleus muscles were dissected out and processed according to the Falck-Hillarp technique; in others, whole brains were assayed fluorimetrically for noradrenaline (NA) and dopamine (DA).

Drug treatment was judged to be effective: treated animals showed characteristic changes in appearance and behaviour¹. There was complete loss of amine-specific fluorescence in reserpine-treated animals, and an increase in fluorescence intensity of aminergic neurones in pargyline-treated animals. Pargyline produced significant increases of 224% in whole-brain NA and 167% in whole-brain DA.

After injection of ³H-leucine, a wave of labelled protein moved along the axons of the sciatic nerve. The velocity of transport was given by the slope of the regression line on a plot of wavefront position against elapsed time. Neither reserpine nor pargyline treatment had any effect on the velocity of transport (Fig. 1). To eliminate the possibility that some labelled protein was transported at higher velocities ahead of the main wavefront, a second series of experiments was carried out.

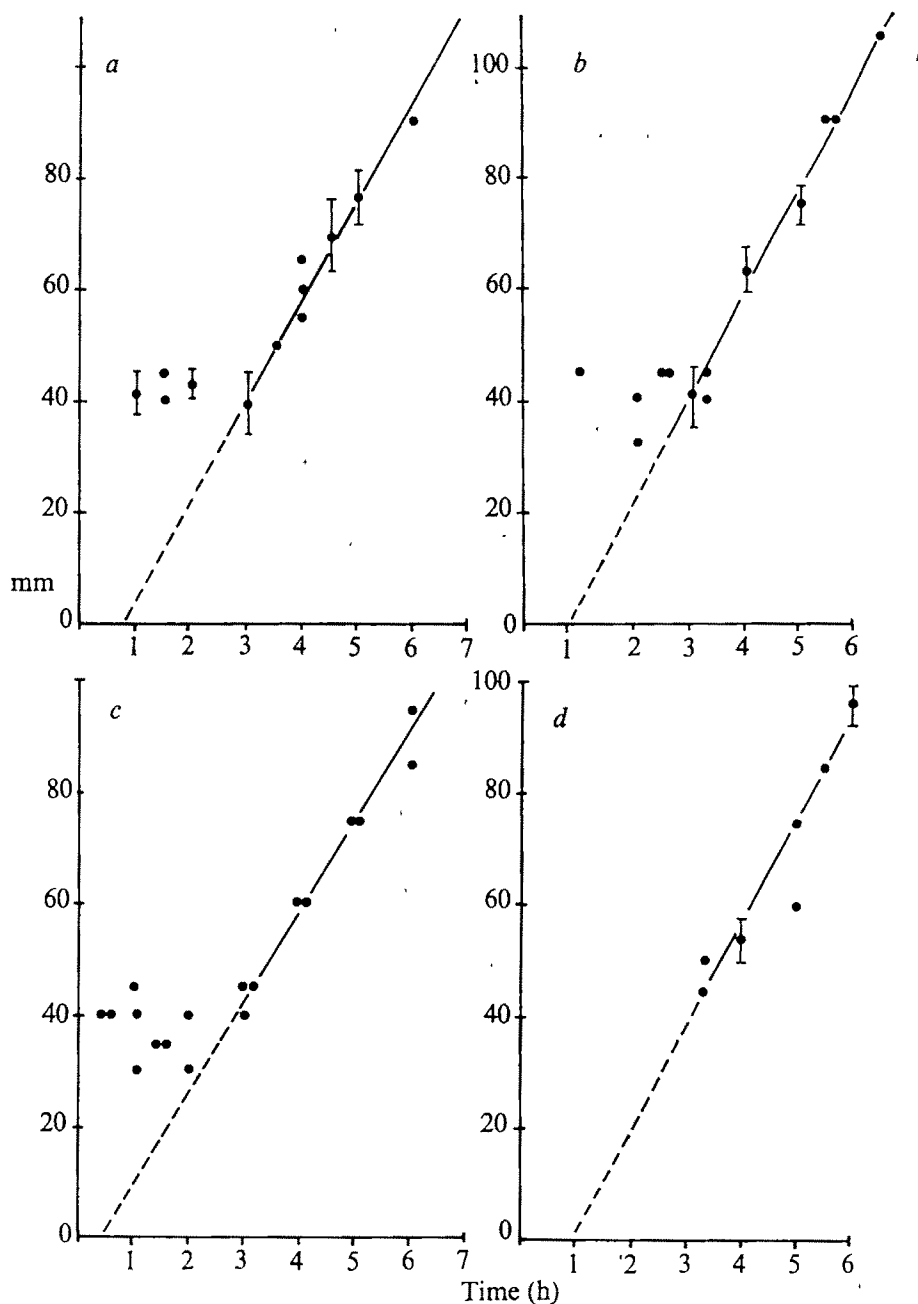

Fig. 1 Velocity of axonal transport. Ordinates, distance of wavefront of activity from most proximal site of injection; abscissae, time elapsed since injection. Where 4 or more points were obtained for any time, the means \pm s.e.m. have been plotted. Regression lines were fitted by the least squares method and were extrapolated to the time axis. Note that at intervals of less than 3 h the wavefront remained stationary at approximately 40 mm from the site of injection. Velocities of transport calculated from the slope of the regression line were: a, controls, 431 ± 16 mm d⁻¹ (mean \pm s.e.m.); b, pargyline (75 mg kg⁻¹), 458 ± 26 ; c, pargyline (25 mg kg⁻¹), 391 ± 69 ; d, reserpine (2.5 mg kg⁻¹) 448 ± 35 .

In a group of rats treated with pargyline (25 mg kg⁻¹) the sciatic nerve was crushed at the time of precursor injection, and the time when transported protein began to accumulate proximal to the crush was measured. The velocity of transport, calculated from the onset of accumulation, was $412\text{--}436$ mm d⁻¹.

At distances of less than 40 mm from the site of injection, the velocity of axonal transport could not be measured reliably owing to the presence in the

ventral roots of high ³H activity (Fig. 1). This activity appeared within 30 min of the precursor injection. Three hours after injection the 'mobile' wavefront broke away from this 'stationary' wavefront and proceeded along the axon. In the region of the stationary wavefront, 50% of the total ³H activity was TCA soluble and presumably represented the diffusion of free ³H-leucine from the site of injection. Beyond the 40-mm limit, which coincided with the exit of the sciatic nerve roots from the

spinal canal, the TCA-soluble activity fell to 10%. Boegman *et al.*² measured total ³H activity and obtained wavefronts located 40 mm from the injection site: there is no indication that they followed wavefronts into more distant regions of the sciatic nerve in order to obtain regression lines for determination of velocity. I suggest that the apparent increase in velocity that they report results from measurements made on a stationary wavefront of diffused activity at shorter time intervals for pargyline-treated than for normal animals.

It therefore seems that changes in amine levels produced by pargyline and reserpine have no effect on the velocity of axonal transport of protein. A further study³ of axonal transport involving manipulation of amine levels requires re-evaluation in the light of these results.

The work in my laboratory is supported by the Medical Research Council of Canada. I am grateful to Ms G. Bilborough and Ms B. Haft for assistance and to Mr L. Baue for the fluorimetric assays. Pargyline (Parsidol) was provided by Abbott Pharmaceuticals.

BOEGMAN *et al.* REPLY—We agree with Bisby¹ that pargyline does not alter the bulk flow of material down the rat sciatic nerve. In our published data² we reported on the total radioactivity present in nerve segments and not the TCA-precipitable activity. This led us to conclude that pargyline alters the rate of fast axoplasmic flow.

We disagree with Bisby's comment¹ that axonal flow rates cannot be measured within the first 40 mm since we have shown that puromycin will abolish a front of TCA-precipitable radioactive material within this distance.

Large scale extinctions

THOMSON'S contribution¹ to the search for the cause of major extinctions points out some patterns of temporal

diversity change that merit consideration. I wish to note an important inconsistency in Thomson's argument and to discuss some work which contradicts his hypothesis of extinction through specialisation.

Thomson mentions that the diversification portion of his diversity curves are typically exponential, not logistic in shape. Later, however, he describes this diversification as "species packing" and consequent niche reduction". Such species packing should result in a logistic growth of diversity², not the exponential one that he notes. Cisne³ demonstrated such a logistic increase in the morphological specialisation of Phanerozoic aquatic free-living arthropods and also showed that diversification accompanies this specialisation, as suggested by Thomson. The apparently broad time intervals used by Thomson may prevent the detection of a logistic pattern of diversification.

That specialised taxa tend to become extinct is one of the most plausible assumptions of evolutionary biology and forms the basis of Thomson's explanation. The only test of the extinction through specialisation hypothesis failed, however, to detect any significant correlation between specialisation and evolutionary longevity within aquatic free-living arthropods³. Furthermore, Thomson's suggestion that diversification (and specialisation) is "entrained" may inadvertently revitalise the corpse of orthogenesis.

Thomson has pointed out some phenomena of major evolutionary significance—the apparent symmetry of the diversity curves and the existence of "group diversity curves"^{4,5}. I agree that it is important to focus on the causes of these phenomena rather than on one striking but merely consequential aspect—extinction.

THOMSON REPLIES—Flessa¹ has read into my highly qualified statements more than I actually said. I merely stated that the diversity curves "approached" an exponential pattern. I tried to explain the curves only by "analogy" with "species packing" and

in any case was working at the genetic level. I do not believe that the patterns of diversification that I described have anything to do with orthogenesis. The question of how one would recognise in fossils the specialisations that could result in extinctions is a very difficult one. Not all specialisations will necessarily be associated with extinction and the reverse is also true. If analogy with any process like species packing can be upheld, it will probably turn out that the crucial specialisations were ones of behaviour and ecology rather than of major external morphology. In that case one might expect morphological specialisation to correlate better with diversification than extinction.

The creeping-film phenomenon of potassium chloride solution

BIN-JUINE HUANG and JEN-CHI HUANG¹ state that the creeping-film phenomenon of potassium chloride solutions cannot be satisfactorily interpreted "based on present knowledge of either surface chemistry or transport theory." We believe the phenomenon can be explained by using ordinary physico-chemical surface forces such as capillary action in a type of 'wick' effect.

Consider a glass beaker containing a saturated solution of potassium chloride; when some of the solution evaporates, crystals form on the sides of the beaker at the surface of the solution. The solution is then drawn up into micro-fissures and crevices in the crystals by capillary action, and when the solution reaches the edge of the crystal formation it wets the glass surface, and on further evaporation forms more crystals which advances the crystal front causing the creeping phenomenon observed. This is analogous to a 'wick' effect where the KCl crystals act as a wick for the solution. This would explain the creeping which occurs over the brim of the beaker.

A saturated KCl solution will exhibit creeping effects when it wets a substrate surface, and this has been observed in a variety of substances, such as glass, aluminium and lucite plastic (A. M. Yacynych, unpublished). It would be difficult to explain this phenomenon by invoking a specific interaction between the solution ions and the substrate surface, in view of the diverse chemical nature of the substances on which this phenomenon occurs. This creeping effect does not occur when the KCl solution does not wet a substrate surface, as is the case with Teflon (A. M. Yacynych, unpub-

lished). Also, creeping does not occur if the KCl solution is unsaturated, or if a beaker containing a saturated solution is stoppered. In the case of an unsaturated solution, if any crystals were formed on the sides of the beaker they would be dissolved as the unsaturated solution was drawn into any fissures or crevices in the crystal and the creeping could not occur. In the case of a covered beaker, no creeping occurs because the atmosphere inside the beaker is saturated with water vapour, preventing evaporation of the solution which is necessary for the crystal front to form and advance.

Regarding the creeping which occurs through a 'seamless' glass tube connector; the authors do not specifically mention whether the joint was greased or ungreased. In the former case, we would not expect any creeping to occur, however, in the later case, small fissures and crevices are certain to be present in the joint allowing the creeping to occur. In fact, this ability of the KCl solution to creep into small fissures is put to good use by electrochemists in constructing reference electrodes². Instead of using a porous frit or a salt bridge to maintain solution contact, a platinum wire is sealed in glass and contact is maintained by way of the small fissures which form between the platinum and glass on cooling.

The alkali halides form two separate isomorphous groups³: the lithium and sodium salts; and the potassium, rubidium, and caesium salts. If the creeping results simply from the wick effect by the crystals, one would not expect it to be unique, and in fact, compounds such as potassium bromide, potassium iodide, and caesium chloride that are crystallographically isomorphous with KCl also exhibit this creeping phenomenon (A. M. Yacynych, unpublished). Sodium fluoride, chloride, bromide and iodide which are not isomorphous with KCl do not creep. Perhaps their crystal formation does not have the small fissures and crevices necessary for the wick action.

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

HUANG and Huang¹ describe the flow of potassium chloride solutions over surfaces and conclude by saying the results are "inexplicable" but that they might be attributed to "interactions of the ions with the surface of the beaker or tube and the surrounding gaseous molecules". In 1950 I observed the same effect in aqueous solutions of potassium ferricyanide, but results of several experiments were not published because I was unable to obtain reproducible quantitative results. I attributed the phenomenon to surface mobility of ions and molecules.

Evidence for surface mobility of adsorbed atoms was first given by Volmer and Estermann in 1921. They set up an experiment in which mercury evaporated from a bath at -10°C to a glass plate at -65°C . Hexagonal crystal plates of mercury formed on the glass. The crystals should have grown at the rate G/p in which G is the rate at which mercury molecules struck unit area of crystal at the glass surface and p is the density of the crystal. But the dimensions of the crystals grew $1,000\times$ faster than that. Volmer and Estermann concluded the

mercury atoms moved over the surface of the glass to become attached to the crystals.

A few years later, Volmer and Adhikari placed a benzophenone crystal between 0.02 to 0.09 mm from the edge of a glass plate; a mercury drop just touched the edge of the glass. The crystal dissolved in the mercury due to the mobility of benzophenone molecules over the surface of glass (vapour pressure negligible); it was estimated that the resistance to diffusion over the glass was one hundredth of that in the liquid state.

Wicke in 1940 was the first to suggest that molecules adsorbed from the vapour phase contribute to total flow through porous materials; and the following year Wicke and Kallenbach flowed mixtures of CO_2 and N_2 past one face of a charcoal membrane, at 600 torr total pressure and pure N_2 past the other face at the same pressure. In the absence of a pressure gradient there was no flow through the membrane but diffusion of CO_2 into N_2 could occur and the diffusion coefficient could be determined by analysis. Experiments were done in the range $0-300^{\circ}\text{C}$. From the laws of gas kinetics, the diffusion should increase with temperature and this was observed at high temperatures. At low temperatures, however, the diffusion coefficient increased as temperature was decreased, which was attributed to the greater adsorption of CO_2 at lower temperatures. Mobility in the adsorbed phase contributed as much as 50% of the total flow of CO_2 at the lowest temperature.

So, when crystals are in contact with another solid surface an adsorbed layer of atoms (or molecules) can form on the solid surface in dynamic (mobile) equilibrium with the crystal. When a vapour (or gas) is in equilibrium with a solid surface there will be an adsorbed phase on the solid in kinetic equilibrium with the vapour; atoms or molecules will be mobile over the surface within the adsorbed phase. Evidence for this is considerable²⁻⁴. Adsorption also occurs when liquid mixtures and solutions are in contact with solid surfaces and various forms of adsorption isotherm have been found experimentally, see for example, Kipling⁵. Atoms and molecules will be mobile within that adsorbed layer.

reviews

Golden jubilee monograph

J. H. S. Blaxter

The Eggs and Planktonic Stages of British Marine Fishes By Sir Frederick S. Russell Pp. xv+524. (Academic; London, New York, San Francisco, 1976.) £19.50.

THERE is a tendency, as fisheries come under increasing pressure, for the success of the fishery to become dependent on the recruit fish rather than on a longer run of successful year-classes. The study of the pre-recruit phases of the life history, both for the purpose of prediction as well as for understanding what determines success or failure of a year-class, then assumes greater importance. This is one of the reasons why investigations of eggs, larvae and juveniles of commercial fish species have been greatly stepped up over the past twenty years. Both sea surveys of these young stages, as well as laboratory experiments involving rearing from the egg, are now part of the standard repertoire of most larger fisheries laboratories, and it is now generally accepted that the year-class strength is probably determined in the first year of life.

It is surprising that no standard work of identification of the young stages of north-eastern Atlantic species has been written since Ehrenbaum's *Eier und Larven von Fischen* which formed the first volume of his *Nordisches Plankton*, produced between the years 1905 and 1909. Many imperfections in identification existed at that time. To a limited extent they were made good in subsequent publications on restricted groups of species such as the gadoids by Johannes Schmidt in 1909, or in more comprehensive descriptions for other areas, as in the Fauna and Flora of the Gulf of Naples during the 1930s and in the ICES plankton identification sheets that appeared after World War II.

Sir Frederick Russell's book thus fulfills a clear need. It is a first class and completely fresh re-appraisal of the identification problem. It covers the planktonic stages of coastal species of northern European waters likely to be found within the 200-m depth contour but it excludes strictly oceanic species. Introductory chapters on terminology, development, principles of identification, feeding habits

and vertical and horizontal distribution are followed by the main section where each teleost family is taken in turn. A description, with key where appropriate, is given for the egg, larva and post-larval stage. Relevant ecological or experimental work is also referred to—one aspect of the book which makes it quite different from previous publications.

The value of the monograph lies therefore in the collation of the taxonomic and other publications, and the assembling and up-dating of the many keys scattered in the literature. During this process the author has brought to bear his unique experience in this field, to improve, clarify and amplify the keys.

The reference to many 1975 and even some 1976 scientific papers in the bibliography is evidence of his success in making the monograph as comprehensive and up-to-date as possible within the range of species adopted. It

is, however, a pity that the style and content of the book, limited as it is to northern European fishes, mean that some of the excellent and relevant ecological and experimental work done, for example, on the Californian sardine and anchovy, has perforce had to be excluded.

Sir Frederick Russell retired from the directorship of the Plymouth laboratory in 1969 and this monograph is a *tour de force* representing the results of his enviable energy during subsequent years. He published his first paper on fish eggs and larvae in 1926 so that the monograph is a fitting and admirable golden jubilee offering to the scientific community. We all look forward to the celebration of his diamond jubilee! □

Dr Blaxter is a Senior Principal Scientific Officer at Dunstaffnage Marine Research Laboratory, Oban, Argyll, UK.

Energetic ion beams and sputtering

Ion Implantation, Sputtering and Their Applications. By P. D. Townsend, J. C. Kelly and N. E. W. Hartley Pp. ix+333. (Academic: London and New York, June 1976) £13; \$32.25.

IN a great many practical situations the behaviour of a component depends on the near-surface composition, physical state or topography of the material. Examples spring to mind in the optical, mechanical, electrical and corrosion fields, and the extraordinary developments in semiconductor devices and circuits involve a sophisticated control of material properties within a layer a few microns thick.

Diffusion, coating and etching have hitherto been used to control surface composition and its lateral variation, but these are no longer precise, versatile or reproducible enough for some requirements. The past decade has seen the development of an entirely different set of techniques based on the use of energetic ion beams by means of which chosen atomic species can be injected into a surface, or, by sputtering, material can be removed.

This book provides a very timely review of the progress achieved so far

in a field in which industrial applications are being extended as each month goes by. The fundamentals of the subject are treated admirably, from the slowing-down of the incident ions to their effects on the target structure. The treatment of applications is more superficial, but the authors must be conscious of the speed with which a detailed account would become outdated. Readers, and there will be many, who are mainly interested in the ion implantation of semiconductors will be disappointed: the literature of this is now so extensive that the authors, perhaps wisely, have chosen to concentrate on the remainder.

A bonus, for which the reader is not well prepared by the title of the book, is a lengthy and most useful chapter dealing with the analytical applications of ion beams.

I congratulate the authors on their clear and readable treatment, and the publisher for the attractive presentation of text and diagrams.

G. Dearnaley

Dr Dearnaley is a member of the research staff at the Atomic Energy Research Establishment, Harwell, UK.

Describing the brain

Cell Biology of the Brain. By W. E. Watson. Pp. xi+527. (Chapman and Hall London, August 1976.) (Distributed in the USA by Halsted: New York.) £15.

THERE have been previous attempts to describe the brain in the language of cell biology, but few have been as crammed with information or as well written as the present monograph. The author has not been intimidated by this heroic task, and has produced an eminently readable and useful volume. The first six chapters give a broad outline of the cellular properties of the brain, its origin from epithelial tissue, the differentiated properties of neurones, current understanding of membranes and their function, and a fairly extensive review of modern knowledge of the 'chemical transducer' mechanisms by which neurones respond to chemical signals.

This includes a description of recent biochemical techniques for the study of receptor sites by the ligand binding approach, the coupling of receptors to cyclic nucleotide mechanisms and more general biochemical changes in neurones associated with activity. In this section there is little emphasis on the neurone as a carrier of electrical signals, nor is there any description of the presynaptic machinery associated with the production, storage and release of neurotransmitters—a deliberate omission since the author rightly points out that these topics are already dealt with extensively elsewhere. But this perhaps leaves some major gaps in coverage for student readers.

The largest chapters, and the most valuable in my estimation, were the remaining four, which deal with the topics of plasticity in the nervous system, responses to injury, neurotrophism and genetics. These are topics which encompass some of the most fundamental problems of neurobiology, and the author is an expert in this area. He gives an excellent review, taking examples from a broad spectrum of vertebrate and invertebrate studies. In dealing with this large area the author deliberately, and probably wisely, avoids the even larger topic of developmental neurobiology, but his deliberate omission of any discussion of the nerve growth factor seemed to me a curious decision.

The book is undoubtedly well referenced. Indeed some might consider that the 3,247 citations in the bibliography (which occupies almost 200 of the 527 pages) were enough for six

volumes of this size. I would personally have preferred to have seen fewer references and more illustrations. Overall, however, there is no doubt that the book is an unusual and valuable source of information on topics that are not well reviewed elsewhere.

Leslie Iversen

Leslie Iversen is Director of the MRC Neurochemical Pharmacology Unit at the University Department of Pharmacology, Cambridge, UK.

Neuromuscular junction

Neuromuscular Junction. (Handbook of Experimental Pharmacology. New Series, Vol. 42.) Edited by Eleanor Zaimis. Pp. xvii+746. (Springer Berlin and New York, 1976) DM 280; \$91.90.

THIS latest volume in this well-known series of reviews and monographs, which all pharmacologists turn to for information when everything else fails, lives fully up to the standards of its predecessors. Each of its chapters amounts to a substantial review article and like others in the series, the book as a whole is full of detail, with each chapter accompanied by an exceptionally complete and valuable bibliography.

The neuromuscular junction is, without any doubt, the most intensively studied synapse of all, it is also a highly atypical synapse, being a simple one-to-one connection between a nerve fibre and a muscle fibre. In life it serves simply as a relay (and a highly reliable relay at that, very rarely affected by disease) and has none of the integrative properties that characterise most other synaptic connections. To some investigators studies of the neuromuscular junction are justified mainly by the implications that the results hold for other more complex synapses. Not to all, though, for at a recent scientific meeting an eminent investigator, asked whether the neuromuscular junction helped to explain brain function, replied that all he could be sure of was that the brain was indispensable in understanding the neuromuscular junction.

This book certainly does not lend much encouragement to the view that the neuromuscular junction is a good model for other synapses. The admirable article by MacIntosh and Collier on the metabolism of acetylcholine makes a point of comparing the results of work on the neuromuscular junction, where electrophysiological

techniques have generally proved much more valuable than biochemical techniques, with work on the brain, where the reverse is true. The differences between the two are a good deal more obvious than the similarities, and the authors comment gloomily: "The extent of these peculiarities of individual tissues... may seem depressing to investigators who would like to think that their results have a general significance and should help to explain all analogous phenomena". Particularly valuable in this article is the balanced discussion of the present status of the vesicle hypothesis. The evidence, which is complicated and often conflicting, is presented with an economy and a clarity which is all too rare in scientific writing.

The following chapter, by Ginsborg and Jenkinson, equally well-written, surveys the mechanism of impulse transmission mainly from an electrophysiological point of view; it, too, succeeds in distilling an immense amount of information into a concise and coherent account. What emerges most clearly from these two chapters is the considerable uncertainty that still exists about the mechanism of acetylcholine release and the difficulty in relating the results of electrophysiological experiments to biochemical events within the nerve terminal. These two chapters, together with the preceding one on morphology by Bowden and Duchon, form the first half of the book and complement each other extremely well.

The rest of the book is concerned mainly with neuromuscular blocking drugs and anticholinesterases. The contentious areas here are the mechanisms of action of depolarising blocking agents and of anticholinesterases, well-scarred battlegrounds on which relatively little new evidence has appeared in recent years. I would have preferred to see less discussion of these topics and fuller accounts of the recent biochemical advances in isolating and characterising acetylcholine receptors. Studies based on these advances have already led to a reappraisal of the nature of the defect in myasthenia gravis and show great promise of leading to a much better understanding of the process underlying synaptogenesis and denervation effects; yet they receive only fleeting comment. The book will, however, be invaluable as a work of reference. The only danger is that it may attract even more experimenters to assault this unoffending synapse.

H. P. Rang

H. P. Rang is Professor of Pharmacology at St George's Hospital Medical School, London, UK.

New Books in the Neurosciences

Techniques and Basic Experiments for the Study of Brain and Behavior

by J. BUREŠ, O. BUREŠOVÁ and J. P. HUSTON.

1976 xvi + 272 pages. US \$23.25/
Dfl. 60.00. ISBN 0-444-41502-5

This textbook and practical guide to experimentation in physiological psychology provides detailed coverage of many of the major problem areas and experimental techniques used in brain and behavior research. Over 50 carefully chosen reproducible experiments covering the traditional research areas of learning and memory, innate and motivated behavior, ablation and stimulation of the brain, electrophysiological correlates of behavior, and pathological states are presented in detail. This book will be an essential acquisition for all students of physiological psychology.

Membrane Morphology of the Vertebrate Nervous System

A Study with Freeze-etch Technique

by C. SANDRI, J. M. VAN BUREN and K. AKERT.

PROGRESS IN BRAIN RESEARCH,
Vol. 46

1976 xii + 388 pages. US \$67.50/
Dfl. 175.00. ISBN 0-444-41479-7

There has been increasing interest in freeze-etch morphology since 1970 but literature has tended to appear in numerous different sources. This is the first comprehensive attempt to present material on membrane morphology by freeze-etch study in a single volume. The result is an amply and beautifully illustrated monograph containing nearly 200 photographs of freeze-etch preparations.

Hormones and Brain Differentiation

by G. DÖRNER.

1976 viii + 272 pages US \$36.50 /
Dfl. 95.00 ISBN 0-444-41477-0

This monograph deduces a number of 'rules' for differentiation in open-loop and feedback control systems, which in turn control a number of fundamental processes of life such as reproduction, metabolism and information processing.

Opiates and Endogenous Opioid Peptides

Proceedings of the International Narcotics Research Club Meeting, Aberdeen, United Kingdom, 19-22 July, 1976

H. W. KOSTERLITZ.

1976 x + 456 pages US \$36.50 /
Dfl. 95.00 ISBN 0-7204-0599-8

The most up-to-date and comprehensive information concerning opiate narcotics, *available less than 2 months after the meeting took place*. For all those interested in the mode of action of narcotic analgesics and the way in which opiates and endogenous opioid peptides react in the central nervous system.

CHARLES C THOMAS • PUBLISHER

APPLIED ELECTRONICS FOR VETERINARY MEDICINE AND ANIMAL PHYSIOLOGY edited by W. R. Klemm, *Texas A & M Univ., College Station. (11 Contributors)* This book presents not only specific electronic techniques, but also briefly explains many electronic fundamentals. The contents are organized around certain topics relevant to the diagnosis of animal diseases and animal research. Included are basic bioelectricity, fundamentals of electronics, electronic measurement of flows, pressures and strains, electrocardiography, electromyography, electronic function of motor function and dysfunction, electroencephalography and echoencephalography. A section on the safe use of electronic equipment discusses the dangers of electric shock, the operation and care of electronic equipment, safety standards, and practical safety guidelines. '76, 484 pp., 236 il., 27 tables, \$31.00

ESSENTIALS OF BACTERIAL AND VIRAL GENETICS by David M. Carlberg, *California State Univ., Long Beach.* Beginning with an introductory chapter on the fundamentals of modern genetics, this book goes on to discuss the chemical and biological nature of molecules responsible for the storage and transfer of hereditary information, the genetic code, polypeptide synthesis and its control, molecular biology of spontaneous and induced mutations, and characteristics and isolation of bacterial mutants. A general discussion of recombination is followed by coverage of transformation and conjugation in bacteria. Genetics of viruses, eucaryotic microorganisms, and the higher plants and animals are also included. '76, 336 pp., 166 il., 35 tables, \$24.75

ENVIRONMENTAL PROBLEMS IN MEDICINE edited by William D. McKee, *Palo Alto Medical Clinic, Palo Alto, California. (36 Contributors)* Understanding the importance of increasing environmental hazards and their contribution to the development of disease is the goal of this book. It covers the population problem, changes in living patterns in modern society, and effects of various hazards and pollutants in our environment. Health effects related to food, water and air in modern societies are discussed, as well as the role of chemical carcinogens, mutagens and teratogens. Specific pollutants such as ionizing and nonionizing radiation, agricultural chemicals and pesticides, and environmental metals are discussed in separate chapters. Special emphasis is placed on the major diseases causing death in our modern society. '75, 880 pp. (6 3/4 x 9 3/4), 90 il., 152 tables, \$36.50

ANIMAL DISEASE MONITORING edited by D. G. Ingram, W. R. Mitchell and S. W. Martin, *all of the Univ. of Guelph, Guelph, Ontario, Canada. (25 Contributors)* The current state of knowledge and practice of animal disease information systems is discussed in this volume. Also presented are mathematical and computer-based epidemiological models of animal disease which will provide much useful information for teaching and policy decisions in animal disease control programs. This volume will also be valuable for providing significant information to optimize animal productivity, minimize losses caused by disease, and guard public health. '75, 228 pp., 40 il., 36 tables, \$21.50

Insects and the Life of Man

224pp Hardback: £6.00 Paperback: £3.25

This distinguished scientist presents to a general audience the fruit of his thinking spanning fifty years involved in research and applications of entomology. The essays and addresses presented here touch on the relationship between science and the economy of mankind, share some of the excitements and intellectual rewards of scientific research and describe important contributions insect studies have made to ecology, medicine, agriculture and the life sciences.

A GUIDE TO RADIATION PROTECTION

J. Craig Robertson

A guide for the layman faced with the problems of dealing with radioactive materials during the course of his work. Assuming no previous scientific knowledge, the book discusses, amongst other things, different types of radioactive sources and how to shield the various radiations they emit.

October 1976 £4.95

Extragalactic astronomy

Galaxies and the Universe. (Stars and Stellar Systems: Compendium of Astronomy and Astrophysics, Vol. 9) Edited by A. Sandage, M. Sandage and Jerome Kristian. Pp. xxii+818. (University of Chicago: Chicago and London, 1976.) £30; \$45.00.

It is 50 years since Edwin Hubble discovered Cepheid variable stars in the M31 galaxy, an epochal step in surveying the extragalactic universe, 21 years since this series was conceived, and 14 years since Allan Sandage commenced the editorial work for this book. The result is a book which is a product of the 1960s and which contains articles completed between 1965 and 1973, with a mean epoch of 1970. Is a book six years out-of-date worth £30?

Fortunately that is an improper question: the 19 chapters are written by people with the highest reputation, each contributing in a field in which he or she is an expert. As Sandage rightly says in his preface, one remarkable feature is the enduring quality of the chapters, which are definitely not out-of-date, although some (for example, quasars, clusters, radio emission) are certainly not up-to-date. The editorial brief was to provide a compendium of essential facts about the Universe, and this policy has ensured that ephemeral theoretical playthings and tentative observations of implausibilities have been kept to the irreducible minimum. Not an easy task in extragalactic astronomy!

Galaxies and the Universe provides a review of well-established knowledge on the observed properties of galaxies and quasars. Individual chapters discuss the contents, masses, magnitudes, colours, sizes, energy distributions, and radio properties of galaxies and quasars. There are also extensive contributions on the dynamics and structure of galaxies. Observational cosmology is dealt with in sections on the distance scale of the universe, the distribution of galaxies, and an impressive review by the editor entitled "The Redshift".

The style is that of a review addressed to an informed reader, and there are very extensive bibliographies: Over 1,000 astronomers feature in the Name Index, and 1,200 objects in the Galaxy Index: these statistics give an impression of the ambitious scope of the work.

Galaxies and the Universe stands as a fitting synoptic monument to a heroic age in the quest to explore the Universe. Here are the results of a golden half-century that successively established the existence of island galaxies

beyond the Milky Way, the redshift, radio galaxies, the cosmic background radiation, and quasi-stellar objects. The nature and history of the Universe on the largest scales is now yielding to the methods of science, and the main thrust of astronomical research for the rest of this century will be among the galaxies. Here in broad outline is a competent summary of what we know about those remote objects, and an indication of what we need to find out. It is an absolutely invaluable work of reference for anyone working in the field and an essential purchase for libraries. It is probably the most significant astronomical book published this year.

Amphibian physiology

Physiology of the Amphibia Vol. 3. Edited by Brian Lofts. Pp. xiv+644. (Academic: New York and London, July 1976.) \$58.50; £35.70.

BECAUSE of their phylogenetic position and varying degrees of adaptation to life in two media the Amphibia are a group with which comparative physiologists are rightly very much concerned. In this, the presumably final, volume of *Physiology of the Amphibia*, the somewhat scattered literature in several fields is brought together and critically reviewed. The completed series now constitutes a source of information which should be indispensable to all herpetologists who are physiologically inclined. The timescale for the appearance of the various parts has, however, been unduly extended and it is a measure of the advances which have been made in some aspects of the subject in the intervening twelve years that there are articles on metamorphosis in both volumes one and three. Regrettably the prices of these same two volumes are an even more striking testament to the pace of inflation.

The present volume covers integrative aspects such as colour change (J. T. Bagnara), moulting (L. L. Larsen) and resistance to desiccation (E. Elkan); cell culture (K. A. Rafferty) and immunity mechanisms (E. L. Cooper); general neuroanatomy (A. Oksche and M. Ueck); more specialised articles on the visual (D. Ingle) and auditory (R. C. Capranica) systems; and finally metamorphosis, with special emphasis on its biological and eco-

logical aspects (M. H. I. Dodd and J. M. Dodd). The declared editorial policy has been to group related topics in the same volume but perhaps inevitably the final one seems to be the most heterogeneous, although there is more interrelation between some of the chapters than might at first appear. For instance it is helpful to have the account of the neuroendocrine systems alongside the discussion of the role of neurosecretion in metamorphosis.

The authors of the articles on cell culture and immunity mechanisms both stress the advantages of using amphibian material for general work in these fields; if this should lead to stocks of Amphibia being maintained in more laboratories, then the homily on amphibian husbandry in the chapter on pathology (E. Elkan) is very timely. At least as far as the more terrestrial species are concerned it must be realised that Amphibia in captivity are pathological specimens unless the conditions closely reproduce those found in the natural habitat.

The book is well produced and printing errors are rare, and then only of a minor nature

Immunobiology of reproduction

The Immunobiology of Mammalian Reproduction. By A. E. Beer and R. E. Billingham. Pp. xvi+240. (Prentice-Hall: Engelwood Cliffs, New Jersey, 1976.)

In their preface to this volume, Beer and Billingham point out the absence of any previous concise, but comprehensive, account of the principles of the immunobiology of reproduction. There is of course good reason for this deficiency. A problem which requires considerable knowledge and understanding of subjects as diverse as immunology, oncology, reproductive and developmental biology, genetics and endocrinology makes discussion hazardous if the authors are not to be caught in the crossfire of experts. That this demanding combination of talent and expertise is required is testimony to the fundamental importance to biology of the problems under consideration. If we are to judge this ambitious work by the authors' professed aim to make good the existing deficiency, we can consider the volume as at least a qualified success.

Not surprisingly, the authors cover comprehensively that data on immunological aspects of foeto-maternal relations available up to mid-1975. This area, in which the authors have both made a major experimental contribution themselves and stimulated new theoretical approaches, is considered critically and with a balanced combination of clinical and experimental evidence. Wide and important issues are covered, such as the possible reasons for a highly polymorphic system of tissue antigens and the resistance to rejection of the foetus or its malignant derivatives. Although a great deal of data is presented, it is, however, often in a form not conducive to logical exploration of the problem. For example, discussion of the question of trophoblast antigenicity was dispersed to several points in the text for no obvious reason, and at times this led to an impression of repetitiveness even when new information was imparted. At the end of this series of chapters, one was left with an element of intellectual indigestion, as though the authors had not had sufficient time to complete their synthesis of the data and analysis of the problem. We certainly do not gain a clear impression of either current opinion or the authors' opinion on the mechanism by which the mammalian foetus survives *in utero*.

Elsewhere in the volume there are some important omissions for a book

on immunoreproduction—for example, immunity to the hormones of reproduction and to ovarian tissue are not considered at all, and immunity to products of the male genital tract are discussed rather briefly. It is also evident, understandably, that the authors are ill at ease in discussing some aspects of the subject. For example, in the chapter on reproductive biology, the impression is given that uteri of all species secrete blastokinin, that the function of this protein is agreed and that 'gastrulation' occurs in the oviduct.

In spite of its deficiencies this book will be a useful source of reference for those workers actively engaged in the investigation of this problem. For others with a more peripheral interest in the subject of immunoreproduction, the volume may prove rather hard work, but will acquaint them with the varied, rather confused, but immensely exciting problems of such central importance to biology.

Conversations in culture

Neurophysiologic Studies in Tissue Culture. By Stanley M. Crain. Pp. xii+280 (Raven: New York, 1976.) \$25.50.

It is indeed a pleasure to rely on the insight of someone with almost 15 years of experience 'listening' to the conversations which nerve cells carry on in culture. Crain has put together a strong concoction of his own data as well as several others' in the field. He has added spice through description of his role as a kind of ambulance driver to transport the live cultures through hectic New York City traffic.

The monograph begins with an orientation which relates his approach to that of others in the study of brain electrical function, and includes a brief historical note on the progress through which recording from cultured cells has grown. The second chapter deals briefly with methods of growth of cells and techniques for recording action potentials with either extracellular or intracellular electrodes. The author then details the synaptic potentials which have been obtained from dorsal root and sympathetic ganglia.

The major portion of the book is then concerned with recording from explants of central nervous system tissues. In each case the recordings amply demonstrate both the prolonged slow wave effects of stimuli, the oscillatory after-discharges and the excitatory and

inhibitory post-synaptic potentials. The electrical tracings are well salted with both light and electron microscopic correlates.

The technique of dissociating brain into single cells and then studying their electrical activities in culture is only a few years old, relative to explants, but the dissociated cells have revealed that their behaviour is quite similar to that of the traditional explants. Once again, Crain discusses the peripheral nervous system as distinct from the central nervous system.

The next chapter deals with responses to various pharmacological agents, including curare, strychnine and bicuculline, as antagonists to the major transmitters, acetylcholine, glycine and GABA, respectively. There is a useful discussion of the results of serum from patients with multiple sclerosis and animals with experimental allergic encephalomyelitis. These sera have complex effects on both neurones and myelin. He then deals with the possible relationship of spontaneous fluctuations in electrical activity to the electroencephalogram. This is followed by a discussion of the important question of longer term 'trophic' interactions of neurones and the cells with which they synapse. Unfortunately, the consideration of the important 'supportive' role of glia is examined in an earlier chapter; one is therefore obliged to shuffle back to obtain the best synthesis. However, Crain certainly appreciates the relevant functional as well as developmental significance of the 'neuro-glial' unit. These findings also touch the wider context of nerve-myelin trophism, as in the classical studies of M. Abercrombie and J. Z. Young.

The final chapter, and other sections throughout the book, contain the lessons of many years: beware simple morphological analysis, the need for standardised ingredients in cultures, attention to the state of the media as related to its last change and the importance of cell-cell contacts (that is, cell number). He ends on a positive note when confronted with the exceptional rise in both the number of interested workers and the collateral spin-off to other disciplines. The only obvious 'omission' is the study of the nerve cell lines, but as Crain certainly appreciates, this could be a monograph in itself. This is a masterful synthesis of not only his own extensive experience, but also the best of others, by an acknowledged founder-father of the art.

nature

December 2, 1976

Swords to ploughshares: is it possible?

A NEW initiative is being launched today (December 2) by a group of natural and social scientists to shed some light on public attitudes to disarmament. It originated with M Albert de Smaele, a former Belgian Minister and leading figure in the Belgian Socialist Party, and has been co-sponsored in a personal capacity by a group including Professor V S Emelyanov of the Commission on Disarmament Problems of the USSR Soviet Academy of Sciences and Professor Eric Burhop, President of the World Federation of Scientific Workers.

The group rightly notes that it is difficult to arouse public opinion on security questions because of a 'mistrust of opposing theses'. So it tries instead to frame questions on armament and disarmament rather than peddle answers, and it hopes that by getting these questions to politicians, leaders of industry, trade unions, the professions, the universities, churches and so on it might help to get going again a debate which has noticeably run aground in recent years.

The premise of the questionnaire is that either the expenditure of 60% of all research and development funds and the employment of 50 million people in armed forces is futile and a senseless waste, or that sooner or later there will be the 'ultimate catastrophe'. So, run the (somewhat paraphrased) questions:

- can war solve the tensions dividing political systems?
- with the current balance of power, is security better served by competitive escalation of armaments or by balanced reduction—and might some nations in Europe lead the way in a reduction as an example?
- what course is being taken by political thought? Would a debate in Parliament, or in the Interparliamentary Union be appropriate?
- would you favour a collective, controlled commitment to forbid new scientific projects related to mass destruction accompanied by an increase in socially beneficial research; the first consequence of which would be a ban on underground nuclear testing?

● could a military-to-social transition, retaining full employment, work?

● should there be more denuclearised zones, and what further measures might help halt the arms race?

It would be easy to dismiss the questionnaire as naive, if not loaded. The first two questions are really statements—very worthy ones, of course, but calculated to encourage one to dismiss the whole thing as a leftist propaganda exercise and to read no further. This would be a pity because it really would be valuable to hear a wider range of views than is normally advanced on the question of putting military resources, particularly in research and development, to work in new fields.

The huge stumbling block, it is always claimed, is adequate monitoring. There are thirty years of distrust to be overcome—mainly worry by Western nations that the Soviet Union by the nature of its society and its geography, would be able to continue military development clandestinely. Present signs are a little more optimistic: there has recently been revived talk in the Soviet Union about permitting on-site inspection in nuclear test monitoring. Even so, the sponsors of the questionnaire should leave Moscow in no doubt of the disquiet that monitoring questions are bound to raise when it is research and not hardware that is being observed.

It would, nevertheless, be good to get some intelligent non-doctrinaire assessment of what potential there is within the defence industry for a change in purpose. And the first step in that direction is to see whether there are any good ideas around for how a task so financially, politically and technologically complicated could be fulfilled. If the questionnaire did no more than start a modest debate on changing objectives for the 1980s it might have started something worthwhile. For too long military R&D has been regarded as too sacred to touch. □

Fear of flying

Which country gave away the largest percentage of its GNP as foreign aid in 1974?

Which country has legislated that private manufacturing companies offer 49% of their share to employees?

Which airline flies the longest non-stop scheduled flight?

So runs a recent advertisement for Iran Air, which seems also to have a bit of a public relations job to do for Iran. The country is growing fast, thanks to its oil revenues. Its expenditure on arms quadrupled between 1972 and 1975. And because of its military spending and its oil money, it enjoys good international relations with a wide range of nations. Amongst its ambitions is clearly the development of universities and science and technology faculties the equal of those in the West. But amidst all this bustle, some detect a faint smell of the violations of human rights.

Amnesty International, in a briefing which academics might wish to read before visiting the country (40p from 55 Theobald's Road, London WC1), has tried to put together what is known about political prisoners in Iran. Even their numbers are uncertain, ranging from the three thousand that the Shah himself concedes to the tens of thousands claimed by some foreign journalists and exiles. Torture is admitted to by the Shah, and is clearly common, although evidence is not as forthcoming as in some other countries, probably because of the immense power of SAVAK, the security organisation, and the fear it instils. Justice is dispensed with little regard for human rights to those accused of political crimes in Iran. Execution for such crimes is not uncommon. Is it impossible for a rapidly-evolving newly-rich country to survive without such repression? □

Watching the rivers blow

Vera Rich looks at a USSR river diversion project which may use nuclear explosions

A RECENT resolution of the Central Committee of the Communist Party of the Soviet Union and the Council of Ministers on the need for a more rational use of water resources focuses attention once again on one of the most grandiose projects ever proposed by Soviet civil engineers—the diversion of water from the Siberian rivers flowing into the Arctic in order to augment the shrinking resources of the Caspian basin. The growing demands on Soviet agriculture after a series of disastrous harvests and the falling levels of the Caspian and Aral Seas make an injection of new water supplies into this region a prime necessity if the reclaimed virgin lands are not to return to desert and the inland seas are not to become salt-marshes. Accordingly, the final section of the resolution calls for engineering and environmental studies on the practical measures and possible ecological consequences such a plan would entail.

Massive hydroengineering projects are by no means new in Russia. Peter I (the Great) proposed to link the Volga and the Don via their tributaries, the Kamyshin and the Lavla, by a navigation canal; he was thwarted by the local governor, Prince Galitsin, who maintained that "God had made the rivers to go one way and it was presumptuous in man to think to turn them in another". Peter's daughter, the Tsaritsa Elizabeth, inaugurated a project to link her country retreat of Tsarskoe Selo to St Petersburg by canal, a scheme which was abandoned half-completed when she died in 1762. The most memorable achievement of the Tsarist era involving water concerned not irrigation but drainage—the reclamation of the Neva marshes and the construction, on this unpromising site, of the new capital of St Petersburg. Indeed, the era left no hydro-engineering works comparable with its last great engineering triumph, the Trans-Siberian Railway.

The new Soviet government soon turned its attention to the possibility of remodelling the waterways. In the 1920s, Lenin's formula of "Communism=Soviet rule plus electrification of the whole country" initiated a great drive to construct hydro-electric stations. Even during the Revolutionary war, the possibility of building a Volga-Don canal was so widely discussed that it became the

subject of black humour between Stalin and Voroshilov: such major engineering projects, it was felt, would not only be a spectacular achievement for Soviet engineering, with all the attendant publicity at home and abroad; the motif of religion which had frustrated Peter now reappeared in inverted form. The idea was that intervention to "correct a fault" of nature would be a valuable contribution to the atheist re-education campaign because the haphazard and "badly organised" geography which Soviet engineers sought to rectify clearly could not be the work of an intelligent Creator.

It is difficult to establish precisely when the idea of constructing canals for river diversion first arose. The aura surrounding the concept even now is redolent of the atmosphere of the early days of Soviet rule. By the 1950s it had become a desideratum, in one collection of essays on the future of Soviet science published in 1959, it is referred to almost casually in comparison with more modern and daring proposals like the damming of the Bering Straits or the diversion of the North Pacific currents. But the idea of river diversion, couched always in terms of the future, acquired over the years something of a millennial character comparable in a sense to the final achievement of full Communism rather than something likely to be accomplished within the next few Five-Year Plans.

Emphasising the practical

The new resolution, however, although concerned largely with preliminary work, re-emphasises the practical nature of the project and implies that during the current Five-Year Plan considerable efforts and resources will be devoted to feasibility studies and to surveys and comparison of alternative routes. The "classic" rivers proposed for such diversion are the Ob' and Enisei. According to plans outlined at the International Geographical Congress in Moscow last August a system of reservoirs, pumping stations, canals and tunnels would be built through the Tungai corridor, a depression several hundred kilometers in length. The most promising plan (K. V. Dolgoplov and E. F. Fedorova, *Voda—Natsional'noe Dostoyanie*, Moscow, 1973) envisages a canal from the confluence of two tributaries of the Ob', the Irtysh and Tobol, which meet at Tobol'sk, to

Atrek, close to the Iranian frontier—a distance of some 2300 km. This would allow up to 50 km³ of water to be directed southwards annually.

The main engineering problem would be posed in crossing the Siberian-Asian watershed, which would involve pumping the water to a height of some 75 m. The cost of the pumping would be considerably reduced by allowing the water to drive hydroelectric turbines on its downward gradient. An announcement at the Moscow Geographical Congress indicates that the canals are also to be of navigable depth, which would favour the ultimate cost-effectiveness of the project. Several giant reservoirs (colloquially called "seas") with areas up to 100 km² would be constructed along the Ob', Irtysh, and Tobol rivers to store the water before transmission.

A number of variants of the plan have been worked out. The canal itself could be continued through to Khanty-Mansiisk at the confluence of the Irtysh and Ob', or else (as Dolgoplov and Fedorova show it), water from the Ob' could be forced back up the Irtysh to Tobol'sk by a series of pumping stations. The headwaters of the Ob' and Irtysh are to be joined by a canal already under construction. A sidebranch of the Tobol'sk-Atrek canal could be taken westward over the Urals to feed the Ural river which has insufficient water for the massive irrigation projects planned for its lower reaches.

Such plans have caused considerable outcry among conservationists throughout the world, who fear that a diminution of the inflow into the Arctic Ocean might cause massive environmental changes and even result in a southward spread of the polar icecap. To ecologists not of the doomwatch persuasion, however, such an outcome seems unlikely. The hydrography of the Ob' basin has been extensively studied. The average annual discharge of the Ob' at Khanty-Mansiisk is some 233 km³, almost five times the proposed uptake of the canal. At Salekhard, where the river flows into the Ob' gulf, the annual discharge is 400 km³. The Ob' basin already has a highly developed economy, including the inland port and industrial complex of Novosibirsk and the vast gas and oil fields of Tyumen', Urengoi and Samotlor. Hydroelectricity from the lower Ob' is a fundamental factor in the planned development of these deposits. The Ob' and its tributaries are, moreover, important fish producers.

As even the plans for the lower Ob' hydroelectric station were preceded by a detailed survey of the microclimate of

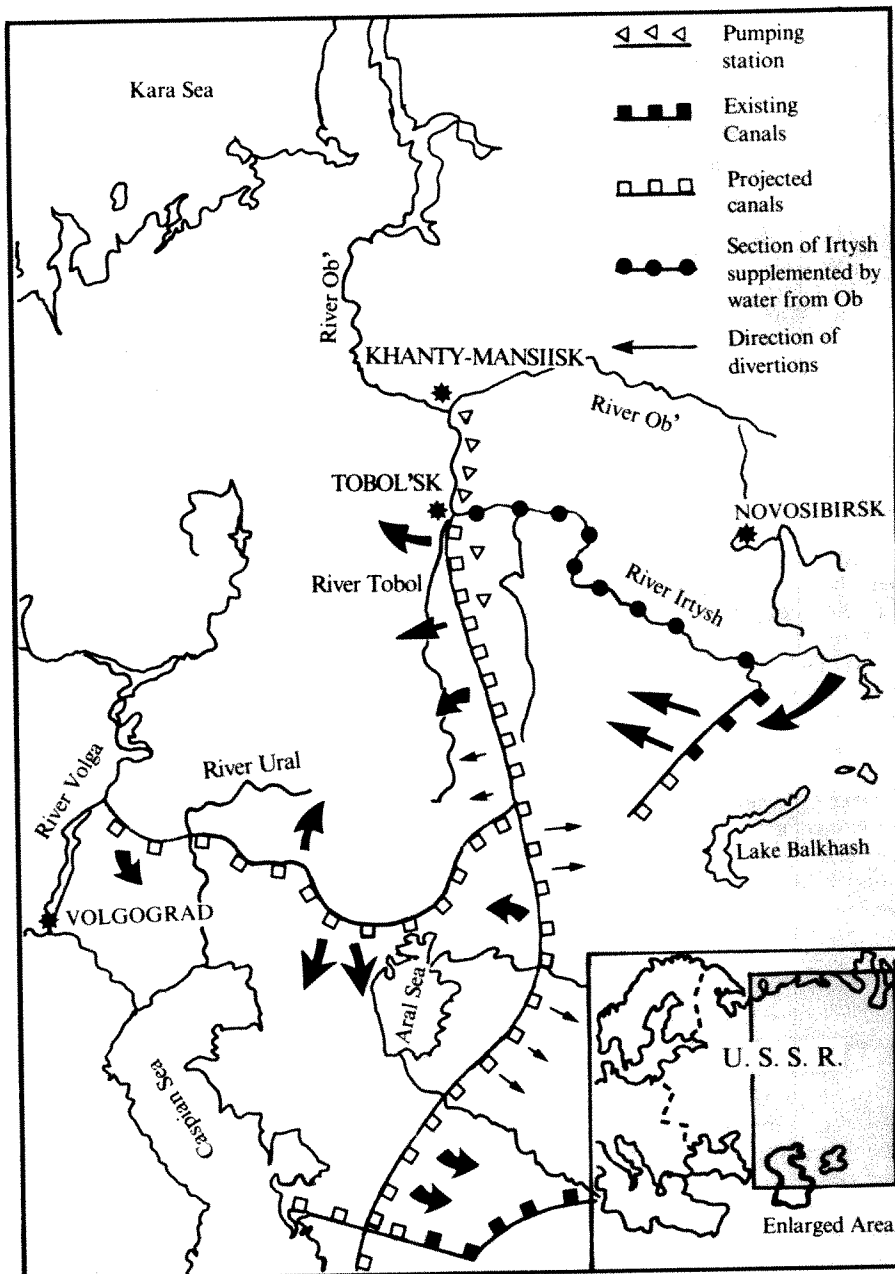

the area, and as the exploitation of the Arctic coast of Siberia is also an important feature of Soviet planning, it would seem highly unlikely that the effect of such proposed diversions would not be investigated as fully as possible. According to the *Novosti* agency, southward redistribution of water from the Irtysh and Ob' (some 75 km³ when all the canals are operational) "would not cause the slightest damage to Siberia". In view of the stress on possible environmental effects written into the resolution this statement may seem somewhat premature, but the emphasis on ecological hazards is significant.

Constructing the canals

Less concern abroad has been evoked by the methods to be used in constructing the canals. Early "spectaculars" of Soviet hydroengineering such as the White Sea Canal were excavated largely by shovel-power and a labour force of "socially undesirable elements" undergoing re-education, but the new canals can command a higher technology—in particular, nuclear explosions. Indeed, such explosions have already been used on another river-diversion scheme west of the Urals which will bring water from the Pechora south to the Kama and thence to the Volga and the Caspian Sea. According to one of the few press articles dealing with this project (it appeared in *Krasnaya Zvezda*, the Red Army newspaper, in 1970), the first stage of canal should be operational by the end of the decade and, with its "cascade" of hydroelectric stations, should recoup all costs within four years.

In view of the fact that, according to Moscow Radio, work on the main canal and reservoirs of the Ob' scheme will not commence until the 1990s, it is interesting that the chief surveyor of the Pechora project, Viktor A. Chistyakov, who had previously worked on the Irtysh-Karaganda canal and the Middle-Enisei hydroelectric station, considered that the terrain of the Pechora project was incomparably more difficult. It is the Pechora diversion which nevertheless seems to have the priority.

The use of nuclear explosives is a feature of the Pechora diggings. The criterion for choosing nuclear rather than conventional blasting is primarily cost-effectiveness; a nuclear charge is more efficient when an explosion of more than a few kilotonnes is required. The Soviet Union has shown an active interest in peaceful nuclear explosions (PNEs) since 1960, when she suggested that a thermonuclear explosion might be used to obtain fresh water from glaciers (the suggestion was not implemented). By using a method of deep-drilling and subsequent collapse, radio-

active products can be confined far below the actual installations, so that there seems to be no great safety-hazard; indeed, a film of an early PNE which formed a crater to be used as a reservoir included shots of a man swimming in the crater only a few days after the blast. (No information was ever released about his subsequent history).

Unlike the United States, which is interested in PNEs principally as a means of gas stimulation and envisages no major construction projects that could possibly employ PNEs, the Soviet Union has in its river-diversion schemes a field where they might play a useful role. It is not surprising, therefore, that the Soviet Union is very interested in the conclusion of a threshold treaty which would define the size and amount of charges to be fired and the conditions under which they may be employed. The proposed treaty, now awaiting

ratification by the US Senate, suggests a maximum charge of 150 kilotonnes, a size which is easy to verify seismologically and which could not be confused with any unauthorised weapon test. If more than one maximum blast is to be used in a single row-charge, a maximum of 1.5 megatonnes is proposed for the row; on-site inspection by the other contracting party would be permitted and, furthermore, that party would be permitted to have monitoring instruments down each borehole to measure the yield. This is the first time that the Soviet Union has expressed a willingness to permit on-site inspection, and may well be an indication of how vital the new canals are to the future Soviet economy. Perhaps the new treaty, with all its political implications, may prove no less a benefit to the canal scheme than the immediate practical gains of irrigation and hydroelectric power. □

At a standstill after a year

Peter Pockley looks at Australian science after 12 months of Mr Fraser's government

NOVEMBER 11, long celebrated in Australia as Remembrance Day to commemorate the end of the First World War, has now been endowed with a second significance. The day was marked in 1976 by large crowds expressing their continued opposition to the manner in which Mr Malcolm Fraser and his Liberal/Country Party coalition persuaded the Governor-General, Sir John Kerr, to sack the Labor Government of Mr Gough Whitlam only two hours after Sir John had laid wreaths on the eleventh hour of the eleventh day of the eleventh month of 1975. Mr Fraser pulled this crisis on Australia, and one month later won the election, on the justification that Labor could not manage the economy.

On his first anniversary in office, Mr Fraser presided over a stagnant economy with his principal target of curbing the 12–14% inflation as much out of range as it was under Labor, with an unemployment rate of about 5% that is the highest since the 1930s and with worse to come as school and university leavers flood the job market in December and January, and with an even worse industrial record than Labor's. Yet his government remains surprisingly popular, a fact which many observers put down to the success with which the release of information and the opportunities for newsmaking debates have been carefully controlled to the point of almost obsessive secrecy. Last weekend's heavy 17½% devaluation of the Australian dollar could dissipate some of that popularity. The Labor Opposition, however, is only just emerging from the shock of its demoralising defeat.

Effect on science

This is the context within which the first Fraser Budget and its effect on science must be assessed. With the one exception of grants for medical research, the effect on science generally has been to impose at least one year of treading water, and quite possibly several years of struggle to stay afloat. Fraser and his Treasurer, Mr Philip Lynch, were determined to tackle inflation principally by drastic cuts in public spending, and their scythe cut deeply into the flesh of all public instrumentalities; unfortunately, most were already lean after cuts by Labor in 1975, and the bones are now exposed.

Take CSIRO, for instance. Its Jubilee year of 1976 has been scarred by a

Budget allocation for 1976–77 of \$131 million (1.6 Australian dollars = £1) which does not even cope with inflation since the 1975–76 allocation was \$123 million. The government claimed the CSIRO's "activities will be held to the same real levels as in 1975–76", a statement greeted with some cynicism by CSIRO administrators as they go about their cheerless task of cutting staff. The foregoing quote from the Budget paper was preceded by confirmation of "an independent external inquiry into the operation of CSIRO". This inquiry is now underway, but as the Budget said, "In the interim CSIRO's activities will be held . . .". It's going to be a hard last period for CSIRO Chairman Sir Robert Price (formerly Dr Jerry Price) and for his unnamed successor who should take over in March 1977.

The 19 universities of Australia are the next greatest sponsors of research. Their growth has been held and there are great uncertainties about the future. Through the Universities Commission, the universities will receive \$562 million for the calendar year 1977, as compared with \$542 million for 1976. The Education Minister, Senator John Carrick, has claimed this constitutes a 2% real growth rate, but no university administrator has publicly agreed; many are trumpeting "hard times ahead". The situation in universities for funding new equipment and replacing old is marginally better than last year, but the real crunch comes in the provision of staff. "Freezing" of establishments and "natural wastage" are the order of the day as universities face unavoidably increasing costs from salary rises as staff grow older on average and are not balanced by equalising intakes of young, cheaper lecturers.

The two principal sources of government money for supporting the research of individuals and small groups, largely in universities, appeared to fare better in the Budget than ever. This was a shrewd, and essentially very cheap, way of the government preventing the kind of damaging outrage which greeted Labor's cuts in these funds in the previous year's Budget. In reality, though, the Australian Research Grants Committee (ARGC) received \$9.1 million, a shade higher only than the previous year. The National Health and Medical Research Council (NH&MRC) was the only group smiling as it received \$9.1 million, a significant increase on \$5.2 million last year; this

Mr Fraser, 12 months on

was a tribute to the success of the public lobbying by the medical researchers, which was not matched by those in the natural and social sciences and the humanities serviced by ARGC.

Individual researchers in academia showed last year how well they could protest at threats to their personal support, but in fact they are far more dependent on maintenance of the overall funding received by their institutions and that is decidedly unpredictable. This is because the government has replaced the triennial system of forward funding of universities with, in essence, an annual budgetary arrangement masquerading under the description of "rolling triennium". Significantly also, the previous triennial forward commitments for ARGC and NH&MRC were quietly dropped and only one-year funding substituted.

The Australian Atomic Energy Commission, under its new part-time Chairman, Professor Don George, faces the year with \$21.1 million, radiated up only \$1.1 million on last year. The Antarctic Division of the Department of Science has been frozen at \$6 million. Industrial Research and Development Grants, administered by the Department of Industry and Commerce, have not developed at all—they have dropped by \$3.9 million to \$15.4 million. Labor's Department of the Environment was swallowed into the maw of a ragbag department called Environment, Housing and Community Development with the deliberate intent of spending as little federal money on environment protection and research as possible. The whole department suffered a shattering 37% decrease in funds and the environment part of it did not even rate a mention in the main Budget documents. Defence science and technology received \$89 million (up \$5 million) out of a total defence vote of \$2,178 million, the only trouble being that nobody really knows what this will be spent on.

Science Department come-back

Reports in these columns earlier this

year chronicled the tribulations of the Department of Science during the first few months of Fraser, when the very continued existence of the Department seemed unlikely. With some good training beneath their skins for survival gained when the Labor Party came to power, the senior staff of the Department knew that if they could survive the first six months of the cost-slashing Liberals they would coast into the period when the new Cabinet aged rapidly as they had to cope with problems of their own making and could no longer blame their predecessors.

This stage has now arrived. But the Department had good reason to be concerned for its future. Its Minister, Senator James Webster, was 25th out of 25 in seniority and his voice was weak in the face of possible Cabinet reshuffles. The Science Task Force of

the Royal Commission on Australian Government Administration had strongly recommended dispersal of the Department's operational divisions among other departments, and there was much support for this view among the scientific community. Fraser had put a hatchet man among the public service to search for and destroy "wasteful and extravagant expenditure", and science was one of those on the block. And there were severe tensions between the Canberra head office and some operational divisions.

In the long run, the hatchets proved blunt and the only waste was the cost of the blades and the unpublished report. The Royal Commission did not come out with a specific recommendation on the Department, and the Secretary, Sir Hugh Ennor, walks taller and looks set to see out his full

term to retirement next year.

Senior members of the Department are setting out to win friends they've not previously had in the universities, at the same time as the Australian Science and Technology Council (ASTEC), a potential rival to the Department in the high stakes of policy formulation, is working hard on its own survival. The Department's data collection outfit, Project SCORE, has its statistics on national R&D expenditure and manpower for 1973-74 at press; official, private inquiries into aspects of research organisation are planned.

The Australian preoccupation with organisations, structures and the dreary politics which go with them to the exclusion of concentration on the substance of research has again been amply demonstrated in Fraser's first year. *Plus ça change* . . . □

CANADA

Reed in the wind

An agreement by the Ontario government to give a paper company the right to cut timber and build a mill in the largest area of the province ever proposed for such a purpose has caused a storm in the provincial legislature. David Spurgeon reports from Ottawa

THE recent controversial agreement between the province of Ontario and Reed Paper Limited covers an area of almost 19,000 square miles, larger than the entire province of Nova Scotia. Although it is subject to the outcome of environmental impact studies and hearings—which, according to the premier, William Davis, will take 2½ years and could still leave the province free to refuse the licence—that has not silenced the critics.

Prominent among them are environmentalists and Indian leaders, and they are led by New Democratic Party leader Stephen Lewis. The "memorandum of agreement" between the province and the company was signed just in time for it to be tabled on the first day of the Ontario legislature's autumn sitting on October 26, and was met by a concerted attack from Mr Lewis. He produced an internal memo from the government's Environment Ministry indicating that some of its own foresters believed the ministry had failed to enforce proper woodcutting practices. The government later said the memo, which warned of a timber shortage by the year 2000, contained only individual foresters' opinions.

The government said the company must submit to a full hearing by the environment board, which heretofore

has dealt only with government projects. All interested parties in the area, such as Indian groups, will be heard by the board. Before that, the company must make public its proposals for a comprehensive forest management plan for its mill, and if the project goes ahead the company must pay back to the government the costs of the studies of timber potential in the area. The agreement expires by January 1980, if the plans are not approved by then.

One of the reasons for the furore is that Reed is the company which owned the chemical plant that was believed to be responsible for mercury discharges into the English-Wabigoon River system, which disrupted life for hundreds of Indians and raised the spectre of Minamata disease among them. The agreement involves some of the same Indians who were previously affected by the mercury poisoning. While those in the area are flatly opposed to the development, which was initiated without consulting them and which would, in the opinion of some, threaten their livelihood, local white residents feel quite differently.

The proposed development would cost about \$400 million and provide up to 1,200 new jobs. It would bring new economic life to the area, whose residents for many years have suffered the uncertainties involved in living in this isolated region. One community is Red Lake (population 2,300), a departure point for rich sportsmen who fly into the area for hunting and fishing. It is also the central housing point for workers in the largest industry in the area: gold mining.

Mr Davis has pointed out that many of those who oppose the Reed develop-

ment have never visited the area and wouldn't know the difference between a balsam and a jack pine. Red Lake Reeve John Goodwillie sees the paper mill as the basis for an economy other than tourism or the vagaries of gold mining. For years the town has seen mines closing and opening, lay-offs and hirings, and market fluctuations. And many agree with him that the mill is a potential boon—not something to be feared. As for the mercury incident, Goodwillie says that as far as he's concerned, "it wasn't Reed that started polluting Dryden, it was a small company and the only thing that Reed did was buy them out and get stuck for cleaning it up."

Ontario's Minister of Natural Resources, Leo Bernier, has in fact been hinting that the company "might just walk away" from the project because of the criticisms. Both Ear Falls and Red Lake councils have passed resolutions supporting the proposed development.

Some see the controversy in a different light. Mr Bernier has admitted, when questioned, that the province is 1½ years behind in its reforestation programme. A paper prepared by an employee of the Natural Resources Ministry raised the spectre of huge acreages going out of production annually as a result of present management practices. It also accused Reed of uncontrolled cutting of Boreal softwoods and partial cutting of high quality stands of Boreal mixed woods.

Public pressure may now force a much more active scrutiny of the province's dealings in many areas, since for the first time a private project in Ontario will have to meet economic tests and numerous environmental, social and cultural tests, too—all of it in public. □

USA

Castles in the air

Colin Norman reports from Washington on a heavily-criticised study from the Environmental Protection Agency (EPA)

A MASSIVE study of the health effects of exposure to low levels of air pollutants, conducted by the EPA at a cost of some \$22 million, is so riddled with errors and shortcomings that the results produced so far are virtually useless. That verdict, reached by a team of investigators working for two Congressional subcommittees, is likely to prove more than a mere embarrassment to EPA, for the study was originally expected to provide the basis for the agency's air pollution regulations.

The study, known as the Community Health and Environmental Surveillance System (CHESS), was an ambitious effort to collect and compare data on the levels of pollutants and the incidence of a variety of health problems in six US cities. Data collection began in the late 1960s and ended last year, and the first results (covering information collected in 1970 and 1971) were published in the form of a monograph in May 1974. The monograph purported to show that there is an association between various health problems, such as the incidence of asthma and heart and lung disorders, and levels of sulphur dioxide in the atmosphere.

Though such a correlation is not exactly surprising—the London smogs of the 1940s and 1950s had provided a rather graphic demonstration of the association between high levels of pollutants and severe health problems—the CHESS findings and the methodology used in the study have encountered considerable scientific criticism.

Most of the criticism has been concerned with the methods used in gathering and interpreting the data, but last February the study was dealt a severe new blow when the *Los Angeles Times* published an article alleging that the finding in the first CHESS monograph had been deliberately distorted by an EPA official "in an effort to prove that pollution from sulphur-bearing fuels has an adverse impact on human health". The article implied that the findings had been distorted in order to provide scientific justification for EPA's air pollution regulations.

The allegations set off a stampede of lobbyists from electricity companies, coal producers and other industries to Capitol Hill, to urge that no new

regulations be adopted at least until the CHESS study has been examined. The matter was urgent because Congress was then about to consider amendments to the Clean Air Act, and consequently two subcommittees conducted a public hearing to examine the charges. The hearing produced a score of witnesses, most of whom flatly denied that any deliberate distortion of the data had taken place. But the hearing did not go deeply into the methodology behind the CHESS study or the validity of the data. For that purpose, a Congressional staff investigation was launched, under the guidance of Congressman George E. Brown Jr, and with the help of a battery of scientific consultants. It was the result of that investigation which was published last week.

The investigating team reported that the CHESS study provides "a picture of a program pressured by EPA management-imposed time constraints to meet legislated mandates for promulgating new standards, hampered by inadequate mechanisms to detect and correct technical problems, and handicapped by budgetary and management restrictions placed on the program after it was well under way". The upshot, Brown said last week, is that the CHESS results published so far "have virtually no quantitative value".

Many of the problems stem from the fact that atmospheric measuring techniques, used particularly in the early stages, are too imprecise to yield good information. For example, an attempt to see whether there is a threshold

level of sulphur dioxide pollution below which health effects are not experienced was hampered by the fact that the measuring technique could not detect concentrations of the pollutant below $25 \mu\text{g m}^{-3}$, and the uncertainty in the measurements sometimes exceeded 100%.

Most of the CHESS data is still to be analysed, but the Congressional report argues that "there is serious doubt that the analysis even when completed will ever be sufficiently credible to support the stated objectives of the program". EPA has, however, initiated a new monitoring program, known as CHAMP (Community Health Air Monitoring Program), which the Congressional report calls "clearly an improvement in aeronomic pollution measurement", but it won't yield health data because at present it is not coupled with a health monitoring programme.

In other words, regulation of air pollution will continue to be based on imprecise information about the effects of low levels of pollutants on human health, a fact which is sure to be exploited to the full by purveyors of sulphur pollutants. They won't have to wait long for an opportunity to state their case, because when Congress returns in January one of its first items of business will be a reconsideration of the Clean Air Act (no agreement was reached last session on proposed amendments to the act, and the matter will be brought up again next session).

It should be noted, however, that although the CHESS study has provided no scientific basis for the present air quality standards, it has provided no reason to reject them. □

Warning on fluorocarbons

Over the shrill objections of the cosmetics industry, the Food and Drug Administration (FDA) and the Consumer Product Safety Commission (CPSC) last week proposed separate actions to reduce and eventually eliminate the use of fluorocarbons in aerosol spray cans. The FDA's proposal, which would involve placing a warning label on fluorocarbon-containing products, was expected; the CPSC action came as a surprise.

FDA has authority over products such as hair sprays, deodorants, perfumes and anti-perspirants, which account for some 80% of the total release of fluorocarbons into the atmosphere. The action announced last week will require the following statement to be printed on the label of aerosol spray cans containing

fluorocarbon propellants:

Warning. Contains a chlorofluorocarbon that may harm the public health and environment by reducing ozone in the upper atmosphere.

No date has yet been set for the regulation to take effect, but barring legal action by the industry to block the proposal, the warning labels will probably be required early next year. The action, noted FDA Commissioner Alexander Schmidt, is only an interim measure—FDA will soon propose a timetable for phasing out all non-essential uses of fluorocarbons entirely.

The CPSC action came in the form of a 5-0 vote by the commissioners to ban use of fluorocarbons in aerosol products not regulated by FDA. No timetable was set by CPSC for carrying out the ban, however.

BRITAIN

Another delay for BNFL

Gillian Boucher reports on the latest developments in the controversy over the reprocessing of nuclear fuel

JUST when they seemed about to gel British reprocessing plans have received a vigorous stir from Mr Shore, the Secretary of State for the Environment, who announced last week that planning permission for expansion at Windscale was to be withheld until he had given it more thought. Cumbria County Council had given British Nuclear Fuels Ltd (BNFL) a provisional go-ahead on November 2 but as the application was outside the scope of the county's development plan it had to be referred to Mr Shore.

If he had done nothing the application would have received automatic approval after three weeks. It was agreed at an inter-departmental meeting on November 15 that Mr Shore would not call in the plans. On the last day on which he could intervene he said he needed more time; by last weekend the House of Commons Select Committee on Science and Technology was considering whether to take up the issue and question Mr Shore itself.

Mr Shore has two choices: handing the matter back to the county council, which virtually means accepting it, as the county council was "minded to approve" the application; or calling it in for his own decision, which will probably mean either a public enquiry or a Planning Inquiry Commission and a delay of at least a year.

BNFL wants to expand and update its Magnox reprocessing plant, develop the process of vitrification of nuclear

waste, and build a new "Thorp" plant for reprocessing oxide fuels. It is this last which arouses such passion because of the large amounts of foreign fuel that it would reprocess. Although it means 1,000 new jobs and around £500 million in earnings from deals with Japan, Germany and Sweden already in advanced stages of negotiation, it also carries the dangers inherent in purifying and transporting plutonium. Friends of the Earth feel that the plutonium peril is so great that oxide fuel should not be reprocessed; but a BNFL spokesman says that although oxide fuel is not as susceptible to corrosion as Magnox fuel, corrosion and leaks into the water in storage tanks will eventually occur if the fuel is not reprocessed.

Mr Shore probably "decided not to decide" as a result of strong pressure for a public enquiry from environmentalist groups. But what he wants more time for is not at all clear. He may want to talk to more specialists or learn the views of Mr Carter. Some critics fear that he is merely waiting for the interest built up over recent weeks to die down before giving his verdict.

He has reserved his decision on the whole of the planning proposal, not merely the oxide plant. But the reprocessing of Magnox fuel cannot be delayed and according to BNFL a refusal on that would result in the premature closure of the Magnox nuclear power stations. A decision on the oxide plant is not as urgent because spent oxide fuel can be stored, but Britain already has two oxide-consuming AGR reactors in action. A ban on oxide reprocessing would force Britain

to take its oxide fuels elsewhere for reprocessing and mean the loss of potential foreign business.

Though nobody would deny the gravity of the problems involved, BNFL is understandably irritated that the government should be stalling 8 months after giving it permission to seek foreign deals—permission which was supposed to have been preceded by adequate debate of the issues. And J. C. C. Stewart, Deputy Chairman of the Nuclear Power Company, said at a British Nuclear Forum Conference last week that it would be "absolutely appalled if the matter did not go forward".

One possible further hurdle, though, lies in the financing of the oxide plant. Last July the government approved BNFL's proposed investment in the Magnox fuel plant and vitrification development, but it has not yet decided whether to act as the lender of last resort for the oxide plant. Most of the finance, however, would come from prepayments from the foreign countries with whom the deals are being negotiated.

Meanwhile the Cumbria council itself may not be allowed quickly to forget its decision. Friends of the Earth and the Lawyers' Ecology Group believe that it behaved improperly in not considering such aspects of the application as the transport of nuclear fuels and the build-up of radioactivity. Mr Shore had written to the council confirming that these were matters for the government, but according to the Lawyers' Ecology Group this does not absolve the county council of its duty to consider the questions. Several pressure groups are likely to come together to take legal action against the council if the planning application is not called in. □

Animal anxieties

BRITAIN'S Medical Research Council (MRC) found it necessary to release a statement last week in an effort to quell a growing storm at its Laboratory Animals Centre at Carshalton, Surrey. The row is over the MRC plan to charge the 70 animal breeders participating in a 26-year-old accreditation scheme the full economic costs of the £70,000 service provided.

The Council said it reaffirmed the importance it attached to its policy, but said it "has been made aware" of the problems in relation to charging for the scheme and had therefore set up a committee with the "necessary powers to act" to review these urgently. It is thought that the committee could report in weeks rather

than months.

Last week, however, delegates from nine trade unions represented at the Carshalton centre called a press conference just as the Council itself was about to meet. They said that if as they expected the Council decided to set up a working party they would have no confidence in this as it was "not a way to proceed". Industrial action was being contemplated, and one union had already asked the Minister of Education and Science to intervene.

The scheme is voluntary and consists of grading, by their degree of freedom from microorganisms, some 3 million animals used every year for research and teaching in labs up and

down the country. The unions say the scheme is now in danger of breaking down totally because the majority of breeders, apparently unable to afford the charges, are threatening mass resignation.

This, they say, would result in "the loss of public control over the commercial breeding of laboratory animals" and could cost the community more than it saves insofar as the use of non-accredited animals grows and leads to costly outbreaks of disease that might not otherwise occur. There is no clear sign, however, that the MRC actually wants the scheme to end, and it seems likely that the new committee will seek ways to maintain it while introducing charges.

Chris Sherwell

IN BRIEF

Environmental warfare action

The Natural Resources Defense Council (NRDC), an environmentalist organisation, has gone to court in an effort to block ratification by the United States of an international treaty prohibiting some types of environmental warfare. NRDC lawyers have argued that since the treaty, which is now being considered by the United Nations General Assembly, would exclude only environmental modification techniques which may have "wide-spread, long-lasting or severe effects", it would not outlaw use of such techniques as cloud seeding and other potentially more damaging environmental modification efforts. If the treaty is ratified, NRDC asserts, it would serve only to "legitimise the use of weather modification and defoliants as weapons of war".

Similar criticisms have also been ex-

pressed by countries including Japan, Sweden, Pakistan and Yugoslavia. NRDC is seeking a novel way to block US ratification of the treaty: it is arguing that the National Environmental Policy Act requires the State Department to file an environmental impact statement setting out the risks and benefits associated with the treaty, and until such a statement has been published, NRDC is seeking an injunction to prevent US ratification.

Windmill site chosen

A small town in New Mexico has been chosen as the site for the world's largest electricity-generating windmill. The Energy Research and Development Administration (ERDA) last week announced that a 200 kW wind turbine generator will be constructed next year in Clayton, a small town with about 3,000 inhabitants in a windswept

region of the Great Plains. The turbine, which will be field-tested for two years, will be the first wind turbine to be constructed in more than 30 years for generating electricity for public consumption in the United States. It will be followed in the early 1980s by two 1.5 MW generators in other, as yet unannounced, locations. Designs for those two generators are now under development by ERDA and, when constructed, they will be the largest wind generators ever built.

Bomb at Swedish plant

A 25 kg bomb at the Ringhals nuclear power station on Sweden's west coast was discovered last weekend after a Göteborg newspaper received an anonymous letter. The bomb was apparently too far from the reactors to have damaged them but could have damaged power lines and transformers.

THE media are providing news of the furbish lousewort (*Pedicularis* sp.). This is a scrophularious plant that is not yet on the endangered list, but is about to receive its diploma in this category, come 1977. Louseworts were so named in England because it was alleged that "the cattell that pasture where plenty of this grass groweth become full of lice". It seems that about 30 furbish louseworts were discovered in the juggernaut pathway of a new federal electric power dam in a remote corner of northern Maine. Such an event sets up two groups: good guys (lousewort lovers) and villains (power dam protagonists) on opposite sides of a "two-valued orientation". The law does not permit a compromise of moving lousewort clusters to another niche in Maine.

Nostalgically I recall that more than twenty years ago I wrote a short article deploring the march of high tension lines through the wild Ramapo mountains, a home of white-tailed deer, mountain laurel, rattlesnakes and blueberries, only 30 miles north of New York City. Like most protesters, I was then, as now, a great consumer of electric power. I am also a lover of the more common louseworts, whose curly fronds rise in reddish sprouts from the wet mud as soon as the snow melts in high mountain meadows. Later they will unfold their small luminous pink flowers called "elephant heads".

It is important to preserve endangered species, but whether we can preserve their present habitats may be doubtful. Sometimes the niche is at greater risk than the species, which can be transferred elsewhere, as with

some of the noble silva of California. The giant sequoia is indigenous in only a few groves on the western slopes of the Sierra Nevada. Yet its lovers have carried it to distant parts; it towers above native trees on the shores of the Vierwaldstättersee in Switzerland. Specimens of its cones

Endangered species

THOMAS H. JUKES

and branches first reached Europe in 1853, and now two giant sequoias in the garden of a palace in Spain are presumably the tallest trees in Europe. If cherished, they can increase in stature for two thousand years. The coast redwood, a similar species, is probably regarded widely as being endangered, but actually it is only the large specimens that are at risk; the species itself is vigorous and thriving. A two-day hike through the Cali-

fornia coast range near Big Sur impresses one that there are probably, and fortunately, more redwoods (small ones) than people in California.

Surely the skills of horticulturists and plant scientists should be increasingly summoned to preserve endangered plant species. Cloning, asexual propagation and transplanting can all be used. The problems are different for animals. Much praiseworthy effort is currently taking place in zoos to save rare and dwindling species of animals, but, when preserved, where will they live? The inherent behaviour of an individual species towards people may either favour or endanger its survival. In the 1920s, the ornithologist Dawson said that there were 20-odd giant condors left in the USA and that one of their principal enemies was "scientists". If the 1920 figures were correct, the numbers of this bird have not since diminished, but it seems to have lost its ecological niche because of human intrusion, and, perhaps, diminution of food supply. Its smaller relatives, the vultures, are in contrast highly adaptive and proliferative. They even eat carrion on the roads in the form of dead animals killed by highway traffic. But the shy and lonely condor will have none of such contact with the doings of humans.

No regrets have yet been voiced over what we are told is the impending extinction of the smallpox virus. Doubtless this little piece of DNA helped, years ago, to keep the human population curve from ascending too steeply. But admirers of smallpox will find few sympathisers.

Is HnRNA really pre-mRNA?

from Bob Williamson

THE central dogma (and much experimentation) convinces us that genetic information in animals and plants is encoded in nuclear DNA, copied into messenger RNA and then translated into proteins in the cytoplasm. Therefore there has to be an intermediate, a nuclear RNA molecule (the primary transcript) which includes mRNA sequences and which is processed into the cytoplasm. This idea, postulated and elaborated by Scherrer and Darnell in particular, has been widely accepted for many years, yet is supported by remarkably little evidence.

A large proportion of the RNA isolated from nuclei consists of large molecules some 10 to 20 times the size of mRNA. This is particularly true when pulse-labelled RNA, which has incorporated radioactive precursors for a matter of minutes, is examined. Much of this large nuclear RNA (known for many years as heterogeneous nuclear RNA, or HnRNA) falls apart when denatured, demonstrating that it is nicked and held together by hydrogen bonds—or perhaps is aggregated *in vivo* or during isolation.

The paradox of the rapidly labelled HnRNA is that, as Henry Harris pointed out 15 years ago, the great majority of it is broken down in the nucleus and never reaches the cytoplasm at all. Cytoplasmic mRNA accumulates very slowly, and no one had convincingly demonstrated a precursor-product relationship between HnRNA and mRNA using radioactive labelling. The major problem has been the mixture of different RNA species present in nuclear RNA. Even in erythroblasts, where the protein synthesised is mainly haemoglobin, less than one part in a thousand of the nuclear RNA is globin mRNA—and the nature of the other 99.9% is unknown. Attempts made by Scherrer and John Bishop in particular to assay for specific mRNAs using labelled cDNA demonstrated the presence of globin mRNA in large duck nuclear RNA, but in such small amounts as to raise some doubts as to possible contamination or spurious cross-hybridisation. These doubts were

stimulated by the fact that McKnight and Schimke (*Proc. natn. Acad. Sci. U.S.A.*, **71**, 4327; 1974) in a very careful study, failed to find a nuclear high molecular weight precursor for ovalbumin mRNA, as did Lizardi (*Cell*, **7**, 239; 1976) for silk fibroin gene transcripts. The doubts were summarised recently in a review by Davidson and Britten (*Q. Rev. Biol.*, **48**, 565; 1973).

The most recent study on globin nuclear RNA (in this case from mouse foetal liver) again demonstrates a small amount of "precursor" double the size of the 9S mRNA (Ross, *J. molec. Biol.*, **106**, 403; 1976). The half-life of the precursor is approximately 45 min. No precursor more than double the size of the mRNA was found using cDNA to hybridise across a 98% formamide denaturing gradient. The undoubted experimental care shown by Ross only serves to emphasise that this type of experiment cannot extend our information about HnRNA beyond Scherrer's conclusions of 5 years ago—the "noise" due to other sequences is just too great.

Advances in this field really depend upon the isolation of specific nuclear RNAs containing only a single mRNA or restricted group of mRNAs. With a defined precursor many questions could be answered: the size of the primary transcript, the significance of the many sequence features (oligo(U), oligo(A), double strand regions and palindromes), the arrangement of unique and repetitive transcripts along the length of the HnRNA, and even the position of the mRNA could be studied. (These cannot be determined now because one has no way of knowing whether the average features of the mixture of HnRNAs really relate to specific mRNA precursors or not).

Several groups have been trying to isolate globin-specific nuclear RNA, and the first report to reach print is that of Curtis and Weissmann (*J. molec. Biol.*, **106**, 1061; 1976). They have used a particularly elegant column chromatography technique which was first developed for the isolation of viral nucleic acid sequences,

and should have wide applications for any mRNA or DNA where a large amount of complementary probe is available. The probe in this case was complementary DNA (cDNA) prepared with viral reverse transcriptase, and then elongated with terminal transferase to put on a poly(dC) tail. This behaves just like 'ordinary' cDNA when hybridising to messenger RNA, or the mRNA sequences in nuclear RNA. Therefore, since globin cDNA was used, it identified and paired with globin RNA sequences only, and with the expected kinetics in solution.

The hybrid, of course, now has a poly(dC) tail. This will bind to poly(G) by specific hydrogen bonds. In practice a close relative of G, inosine (I), which has the same pairing properties, was used. With a poly(I)—Sephadex column only elongated cDNA molecules containing poly(dC) were retained. These will, of course, include any that have formed hybrids with globin-specific nuclear RNA molecules.

It was no surprise to find that much of the globin-specific nuclear RNA in the mouse erythroid Friend cell line is approximately the same size as mature, cytoplasmic globin mRNA. However, when RNA pulsed for 20 min was examined, an additional peak at double this size (approximately 500,000 molecular weight) was also found. This had previously been found in duck erythroblasts and mouse foetal liver as well. Again, little material larger than 15S could be isolated after denaturation. Curtis and Weissmann conclude that their results definitively demonstrate a nuclear precursor RNA containing globin mRNA at least double the size of the mRNA itself. A number of controls, using fingerprint analysis and labelled cytoplasmic globin mRNA, demonstrated both the specificity of the method and the absence of aggregation.

The most important aspect of the Curtis/Weissmann experiments, however, is their wide applicability to all animal and plant nucleic acid systems. At the moment, progress is difficult because of the large numbers of genes

and transcribed sequences. There are some 10 million gene-size pieces in the human genome, and at least 1% of these are transcribed in the nuclei of even the most differentiated cell types, albeit at low levels. The affinity chromatography tricks developed here, and similar ones using cDNA covalently bound to cellulose columns (for instance Levy and Aviv, *Proc. natn. Acad. Sci. U.S.A.*, **15**, 1844; 1976), allow the isolation of one specific DNA or RNA sequence from this plethora.

The emphasis during the past few years on covalent integrity of the nuclear RNA (which has led to so much formamide and DMSO technology in an attempt to denature aggregates) does not answer the real point. It would be quite possible for the very large precursor to be nicked during or shortly after transcription, in which case a small mRNA-containing molecule would be obtained. In fact, this obviously does happen, in the course of normal processing to the cytoplasm. It is most instructive to compare these data on isolated RNA molecules with the sizes of primary transcripts seen with the electron microscope.

Charles Laird and his colleagues (Foe, Wilkinson and Laird, *Cell* **9**, 131; 1976) studied electron micrographs of

chromatin-associated fibre arrays of nuclear ribonucleoprotein from milkweed bugs. The non-ribosomal regions of the chromatin had far fewer "growing RNA chains" than the nucleolar regions, but these still could be measured. Each "active transcription unit" has a defined "start point" (showing directly that there is a specific initiation point for non-ribosomal gene transcripts, in itself a finding of some importance). Moreover, the average size of a non-ribosomal RNA primary transcript is approximately 8 million daltons, very nearly the size originally predicted using non-denaturing gradients. Unfortunately, Laird cannot yet distinguish individual mRNA precursors in the electron microscope.

As for so many other problems in molecular biology, DNA recombinants will enable these questions to be resolved. When a genomic DNA sequence containing the globin gene is isolated, it will then be possible to follow the fate during processing of transcripts of the sequences adjacent to, and progressively further from, the coding sequence. Using the Curtis/Weissmann technique in conjunction with a recombinant, true processing kinetics could therefore be studied for the first time leading to greater understanding of control of eukaryotic transcription.

with a mass of about $2.5 \text{ GeV}/c^2$. This is interesting, because it means that we are apparently observing the spectrum of excited states of the charmed particles, both for the baryons in this experiment, and for the mesons in the e^+e^- experiment. Theorists can therefore begin to test quite detailed dynamical models which may shed a great deal of light on the question of quark confinement and the fundamental nature of the strong interaction.

But the most direct probable observation of charm so far comes as a single event reported this week. (Burhop *et al.*, *Phys. Lett.*, in the press). Physicists from ten laboratories in Britain, the USA, Belgium, Switzerland, France and Italy exposed a stack of nuclear emulsion to the neutrino beam at Fermilab. They used spark chambers and counters to identify the possible neutrino events, and followed the particles seen in the spark chambers back through the emulsion to find the primary interaction points. Nuclear emulsions form the tracks of silver grains along the paths of charged particles, and these tracks can be resolved with a precision of around one micrometre. This is much finer than any other particle detector, and it means that the tracks of very short-lived particles can be observed, not just the tracks of their decay products. The photograph is a mosaic of pictures taken through a microscope of the tracks in the interesting event. A number of heavy tracks, and some very light ones can be seen emerging from the neutrino interaction point A, near the left of the picture. One of the lighter tracks can be seen to travel about $180 \mu\text{m}$ and then split at B into three light tracks, with no sign of any heavy recoil. Although one event can never be uniquely identified with complete certainty, by far the most straightforward interpretation of this event is as the production and decay of a charmed particle. The lifetime predicted by the GIM model is a few times 10^{-13}s , which gives a typical decay length of about $100 \mu\text{m}$, very consistent with the event observed. Detailed measurements on the tracks in emulsion show that there must be a missing neutral particle at the decay point, and examination of the spark chamber pictures has shown convincing signs of a K^0 or Λ^0 decay, within the spark chamber array, pointing back very satisfactorily to the event.

This strange particle may well be the only missing neutral, in which case it is possible to estimate the mass of the particle which decayed. Such estimates require further assumptions about the charged tracks from the decay. Are they pions or kaons? Assuming they are pions, the mass of the decaying

Likely examples of charm

from David Miller

THERE is something very coy about charm. This new quantum number was first invoked to explain the absence of neutral-current processes in the weak decays of strange-particles (see for example, Glashow, Iliopoulos and Maiani, *Phys. Rev.*, **D1**, 1285; 1970; often known as "GIM"). A K^+ meson, for instance, will decay preferentially to a positive muon and a neutrino—a charged lepton system, but a K^0 produces the equivalent neutral lepton system, a positive and a negative muon, with an almost negligible probability. The first experimental evidence for the existence of charm was very indirect; the observation of the new J/ψ family of particles which are now thought to contain "hidden charm" in the form of a quark-antiquark pair. This year the e^+e^- colliding-beam machines have begun to show evidence for the production of pairs of overtly charmed mesons (see for example, Goldhaber *et al.*, *Phys. Rev. Lett.*, **37**, 255; 1976) and neutrino experiments at Fermilab near Chicago and at CERN at Geneva have continued to accumulate events with two leptons and a strange particle in

the final state, which are also usually regarded as examples of charmed particle production (see for example, Benvenuti *et al.*, *Phys. Rev. Lett.*, **34**, 419; 1975; Bleitschau *et al.*, *Phys. Lett.*, **60B**, 207; 1976). Two new results have now appeared to reinforce our belief in the quantum number.

A group from Columbia University, Hawaii, University of Illinois and Fermilab, working in a high energy photon beam at Fermilab, have observed the decay products of a long-lived antibaryon with a mass of $2.26 \text{ GeV}/c^2$. It decays into an antilambda hyperon (Knapp *et al.*, *Phys. Rev. Lett.*, **37**, 882; 1976) and three pions.

The GIM model predicted that the weak decays of charmed particles would produce strange particles, like the antilambda, as a direct consequence of the absence of strangeness-changing neutral currents. Not only does this experiment report the possible "charmed lambda" at $2.25 \text{ GeV}/c^2$, but they see strong indications that it may be produced by way of the decay of a heavier charmed baryon

particle is too low to correspond to the observed charmed mesons (with the neutral taken as a K^0) or the charmed baryons (with the neutral as a Λ^0). If two of them are kaons the mass estimates fit in quite well as either a charmed meson or a baryon. There is no requirement, in any known model, that three strange particles (a lambda and two kaons) should be produced in charmed decays, but there is no reason why it should not happen in perhaps 10 or 20% of events.

This event came from only fifteen neutrino interactions which have so far been identified in the emulsion. The collaboration is still searching for others, but a much larger exposure is planned next year at CERN, where the

new 400 GeV SPS accelerator will be used. Neutrino interactions in the emulsion will be found by projecting back tracks seen in a hydrogen bubble chamber, so the final state particles will be much more clearly identified than they are in the spark chambers. Two or three more events like this one will probably be sufficient to establish, at last, that it is charm that has been discovered. This would not only be satisfying as a vindication of the GIM model; the model is intimately linked with the attempt to unify the theories of the weak and the electromagnetic interaction, so the confirmation of charm will be a sign of real progress in this extremely important programme.

position of the peak response in the array of fibres leaving the cochlea, and intensity by the rate of discharge in the cochlear nerve. The problem arises with stimuli containing several frequencies, because discharge rate has been shown electrophysiologically to saturate at 50 dB, at which level different frequencies should (on position theory) become indistinguishable. But J. P. Wilson and J. Seelman (Keele University) have shown psychophysically that sound level has little effect on the ability of the ear to distinguish the constituents of different sounds (and besides, experience both inside and outside the laboratory amply demonstrates that speech is still intelligible at 70 dB).

Once beyond the auditory periphery, questions of auditory coding begin to overlap with those of visual coding, the central issue being whether single neurones which respond selectively to specific stimulus "features" are a plausible neurophysiological substrate for individual percepts. There have been claims, for instance, that some vertebrate neurones respond specifically to the mating calls of conspecifics.

Those claims, however, are subject to the objections that were raised in connection, for example, with visual "hand-detectors" in the infero-temporal cortex: the methods used simply could not identify such neurones, even if they existed. To resort to *reductio ad absurdum*, on the criteria applied to call-detectors many auditory cortical neurones are white-noise detectors.

More stringent criteria have since been applied by D. Ploog (Max-Planck-Institut) and his colleagues, using the natural calls of squirrel monkeys. Work based on the same principles but with

Sounds and signals

by Miranda Robertson

The Dahlem Conference on the Recognition of Complex Acoustic Signals was held in Berlin on September 27–October 1. A book based on the conference will be published in Spring 1977 and can be obtained from Dr Silke Bernhard, Dahlem Konferenzen, Delbrückstrasse 4c, D-1000 Berlin 33.

IN tackling the issue of how the physical properties of an auditory signal are analysed at various levels of the nervous system to produce a "percept", participants at the meeting were inevitably recapitulating for much of the time arguments that have preoccupied

visual and auditory neurophysiologists for many years and remain unresolved (for an example of the state of the question as visual neurophysiologists left it, see H. B. Barlow, *Perception*, 1, 371; 1972).

But although many of the general questions thus had a somewhat familiar air, some of the specific ones which were addressed exclusively to problems in audition presented a fresh challenge of both theoretical and, often, practical importance.

For example, neural coding is still not properly understood at the auditory periphery, as E. F. Evans (University of Keele) pointed out. It is generally accepted that frequency is coded by the

guinea-fowl was reported at the meeting by H. Scheich (Technische Hochschule Darmstadt), who with G. Langner and D. Bonke has identified the salient features (on behavioural criteria) of several species-specific calls. They tested neurones for selectivity in three ways: with variants of the natural call, with individual salient features of the natural call, and with synthetic calls compiled from those components. They concluded that "call-detectors" consist of neurones with combined selectivity for several call components and which would thus both respond best to natural ("broad-band") stimuli, and tolerate some variation in those stimuli.

An important preoccupation of many of the participants was the identification of the salient features of speech, with a view to the question of whether neurophysiological specialisations exist for speech perception at different levels—for instance, phoneme, word and sentence level. At the level of the phoneme, for example, very small variations in the physical signal can carry enormous linguistic weight. A. M. Liberman (Haskins Laboratories Inc.) and D. B. Pisoni (Indiana University) described work showing that the distinction between "slit" and "split" is made on the basis of the duration of the silence between the "s" sound and the onset of voicing with the "l". "Rabid" is distinguished from "rapid" in a similar way, although other cues (twelve of them) are available to help with that distinction.

At that level, little physiological specialisation seems to be necessary, since chinchillas (which happen to be reasonably sensitive to speech frequencies) do quite well on the rapid/rapid distinction (J. D. Miller, Central Institute for the Deaf, St Louis).

On the other hand, analyses of this kind may be crucial for the understanding of the aetiology of speech problems in children. P. J. Tallal (J. F. Kennedy Institute, Baltimore) reported that the cause of aphasia in some children had been identified as a specific inability to perceive rapidly changing speech sounds—a defect that can be found in adults with certain kinds of temporal lobe lesions.

But while the children can neither understand nor (consequently) produce speech, the lesioned adults can do both. This raises another important point about speech perception. That is that adult speech perception is determined almost as much by experience as it is by the physical speech signal. Pisoni and Liberman pointed out that, for example, coarticulation in normal speech obliterates important cues at the phoneme level, yet speech is still intelligible. That is because the listener already knows a great deal about the structure of language and

(usually) the domain of discourse, and understands the speech stream as much in the light of that as on the basis of its physical properties. Children lack that knowledge and are thus much more dependent on phonetic cues: hence, probably, the difference between Tallal's aphasic children and lesioned adults.

To return to parallels with the visual system, in which the focus of controversy has been how far early experience influences the development of receptive fields, P. D. Eimas (Brown University) suggested that there may be instances in which the auditory system, too, can become biased by early experience. There is evidence that Japanese adults cannot distinguish "ra" from "la" (really); yet Eimas finds that American infants can. Does this mean that all infants can make the distinction, but Japanese ones lose the ability because their language does not require it? Participants pointed out that that question could not be answered until it had been established that Japanese babies could make the relevant distinction, and that the field was fraught with methodological problems because of the nature of the tests on very young infants. A. J. Fourcin (University of London) added that it would be surprising if true, since the evidence says that perception of speech sounds is relatively poor in infants but improves up to the age of 13 or 14.

Plasticity in the auditory system was in fact a topic of extensive discussion, and this report no more does justice to it than it has been able to justice to many other lines of work drawn together by the organising committee under the chairmanship of T. H. Bullock (University of California, San Diego). For reams of fascinating information on echo-location by bats (G. Neuweiler, University of Frankfurt and N. Suga, Washington University), a cogent discussion on whether syntax and categorical coding exist in animal communication (P. R. Marler, S. M. Green, Rockefeller University), and the details of what machines can and cannot "understand" (chiefly M. Schroeder, University of Göttingen) and how to induce them to speak English without a heavy foreign accent—it will be necessary to read the book.

from E. F. Evans

How a scientific study of the biological mechanisms underlying the analysis of complex sounds can aid our understanding of disorders of hearing and language, was the subject of an additional session of the Dahlem Conference on the Recognition of Complex Acoustic Signals. This session devoted most of its time to considering the underlying nature of disorders of hearing and language before moving on to

consider implications for present and future methods of diagnosis and rehabilitation of the deaf.

Because we cannot yet identify all the stages of analysis of speech signals by the auditory system, it is not possible to understand the defective mechanisms responsible for disorders of hearing and language. However, the importance of processing at the peripheral auditory level, and lesions at this level, was stressed. Normal cochlear function is necessary for the correct detection, resolution (in frequency and possibly time), and intensity coding of simple and complex auditory signals, and lesions at this very peripheral level can therefore be responsible for poor speech analysis because of deterioration in frequency response, in peripheral frequency resolution (by which the ear separates out the individual frequency formants of speech), abnormal intensity coding and increased distortion. More centrally, disturbances in temporal analysis (particularly the processing of rapidly changing sounds, including formant transitions) have been shown to underlie speech processing deficits in aphasic children formerly labelled as "language impaired" (Tallal). In other words, the deficits lie in "lower level" acoustic signal processing rather than in "higher level" linguistic domains. Much more work, using the techniques of psychoacoustics and electrophysiology in the laboratory and in the clinic, is required to identify specific defects in speech processing.

It is clear that new strategies in the diagnosis of hearing and language disorders wait upon a more complete understanding. However, new tests are already indicated and are being evaluated. Routine threshold tone audiometry cannot, except in the extreme cases, lead to a prediction of the ability to process speech; on the other hand, the redundancy of the speech signal means that speech audiometry gives little information other than the degree of handicap. New tests are being devised to evaluate the functional state of specific mechanisms of speech analysis, using non-verbal speech-like signals. Thus, tests of peripheral frequency selectivity are being examined; other tests can be devised to evaluate both peripheral frequency selectivity and central pattern recognition (J. L. Goldstein, Tel Aviv University); and a battery of tests is in use to investigate systematically the normality of temporal and spectral analysing mechanisms in patients having impairment of language acquisition in spite of normal pure tone audiometric thresholds (Tallal).

As far as rehabilitation was concerned, great interest was shown in the recent attempts to preprocess speech

signals for patients with peripheral hearing losses, particularly those using filtering and frequency-specific compression, or dichotic presentation of electronically separated formants (W. A. Ainsworth, Keele University). Preliminary results were encouraging, but it is too early to predict the practical outcome for the deaf. Attempts to provide the profoundly deaf with speech information through visual and tactile inputs have proved disappointing, although it is possible to introduce prosodic information such as intonation (important for interpreting the meaning of speech signals) successfully through a multi-channel vibrator prosthesis (A. Risberg, Stockholm University). The restrictions on the rate of information processing presented by the relatively low temporal resolution of the skin and retina indicate that electrical stimulation of the auditory system, for example, by cochlear prostheses, may offer the most likely chance of useful rehabilitation of the profoundly deaf not helped by hearing aids. Present work with single electrode cochlear prostheses is encouraging, particularly for imparting prosodic information, such as the fundamental frequency of speech as indicated by A. J. Fourcin (University College, London). In this way, it ought also to be possible to signal specific speech features such as the "voiced-voiceless" distinction. Both of these should constitute an invaluable aid to lip-reading. However, the full range of speech features required for complete intelligibility can probably only be imparted by multi-electrode stimulation with adequate electrical isolation of the electrodes. This does not seem to be realisable in the foreseeable future.

Honey in the tropics

from a Correspondent

The First Conference on Apiculture in Tropical Climates, was held in London on October 18-20. It was arranged by the International Bee Research Association, in conjunction with the journal *World Crops*. The Conference ended by framing 23 resolutions for submission to international and governmental agencies. A copy is available from the International Bee Research Association (Hill House, Gerrards Cross, Bucks SL9 0NR), together with details of the published proceedings of the Conference. A Second Conference on Apiculture in Tropical Climates is proposed for 1979 or earlier, if possible in the tropics.

The programme at this first conference ranged over topics as diverse as the

chemical nature of bee sex pheromones and the state of development of bee-keeping in Ethiopia. Tropical countries that want to increase their honey production are understandably tempted to import exotic races, strains, subspecies or species of honeybee that reputedly store honey faster and in larger amounts, but several speakers emphasised the difficulties, and indeed the dangers, of doing this. The aftermath of the 1956 importation of a few queens of the tropical African honeybee *Apis mellifera adansonii* into South America is common knowledge.

The European honeybee *Apis mellifera*, an excellent honey producer in many temperate parts of the world, has now been imported into various countries of tropical Asia where the native *Apis cerana* is not very productive. Some of the importations have been inexplicably disappointing. Soekiman Atmosoedaryo reported on a recent introduction of *Apis mellifera* into Indonesia by the Forest State Corporation, of which he is Director. Colonies had dwindled away and died, in a way that was only too familiar to other Conference delegates. Possible reasons include the lack of adaptation of *Apis mellifera* to the many natural enemies of honeybees in the tropics—including other insects, and birds and mites. Also this temperate-zone bee follows a diurnal foraging pattern that is ill adapted to tropical plants presenting their nectar and pollen only in early morning and late afternoon.

N. Koeniger (University of Frankfurt, Germany) reported research that throws light on another difficulty experienced by imported species—that of mating. Queens and drones of any *Apis* species fly during a specific period of the day. If one *Apis* species is introduced into the territory of another, whose queens and drones fly during a period overlapping that of the imported species, the imported queens are unlikely to mate. Local queens, which are far more numerous, produce the same sex attractant as imported queens, 9-oxodecenoic acid, so drones of both species chase them, but only the local drones can mate with them. Most of the drones chasing an imported queen will also be of the local species; they cannot mate with her even if they locate her, but they keep away imported drones which could mate.

Apis mellifera and *Apis cerana* are not known to coexist in nature; if they do so, it would seem likely that their mating flight periods have become differentiated, as Koeniger found with the three *Apis* species present in Sri Lanka.

The management of bees for honey and wax production poses very

A hundred years ago

The directors of the Swedish Government railways have turned their special attention to the frequent occurrence of colour-blindness amongst their engine-drivers and other officials. Prof. Holmgren has lately examined the whole staff of the Upsala-Gefle Railway, and amongst the 266 persons examined has found no less than eighteen who suffered from this defect, and who therefore were utterly useless and unfit for railway service.

A very fine new university building has been erected at Kiel, one marked peculiarity of which is that it has no "carcer", or prison, which hitherto, it seems, has been an invariable appendage to German universities.

From *Nature*, 15, November 30, 110; 1876.

different problems in tropical and in temperate climates. Most of the early studies on bees were made in temperate regions, and perhaps for this reason, bee behaviour there has often been regarded as normal, and behaviour in the tropics as aberrant, yet it may well be the other way round. When the food resources of an area fail, tropical honeybees commonly migrate to an area where forage exists, as entire colonies, leaving their established nests (T. M. Chandler, International Development Research Centre, Nairobi). As a means of survival this migration is an alternative to the massive food hoarding of honeybees which have to survive a winter dearth period.

Jim Nightingale (Sasumua Estates, Njoro, Kenya) has lived with bees in Kenya for 54 years, and he was able to describe bees' migration routes in earlier days when human use of land was sparse and primitive: to-and-fro movements between the highlands and the floor of the Rift Valley—between the Aberdare Mountains and Naivasha, between the Mau forests and the Valley, and between the Kipsigis areas and down towards Lake Victoria. The human population has now upset age-old patterns in Kenya, but Ethiopia is not yet changed. Mammo Gebreyesus (PO Box 30407, Addis Ababa) maintains apiaries in the highlands, and in the Rift Valley 55 km to the east and 1,500 m lower down. He achieves continuous honey production by moving his hives between the two apiaries at the migration periods, so that the colonies do not leave them.

Mammo Gebreyesus is one of Ethiopia's very few modern beekeepers:

of around one million beekeepers only thirty use modern hives. The fact that the country has three million primitive hives exemplifies the scope for modernisation of beekeeping in the tropics. But, in addition, many areas in tropical Africa, Asia and America are grossly underpopulated with honeybees, and nectar and pollen resources go to waste.

After the sessions on bees, bee management and handling bee products (especially honey and beeswax), came the final session on apicultural development programmes, and this could usefully have lasted two days instead of four hours. It was the first meeting between representatives of donor agencies (from four continents), specialists in charge of their beekeeping programmes, and counterpart specialists from developing countries. At least 53 beekeeping development programmes have been or are now in operation. Tecwyn Jones (Centre for Overseas Pest Research, Ministry of Overseas Development, UK), who opened the Conference, stressed the advantages of beekeeping as a family-level exercise for the peasant farmer. It requires little financial input, and only a few square metres of land; it can be undertaken by people of almost any age, and the commitment can be variable, from a minimal spare-time one to full-time professional occupation. Even spare-time, it may well provide a peasant farmer with a much larger cash income than his usual full-time farming gives him. And it is environmentally sound; nectar and pollen are rarely utilised to the full unless there are social bees to take them, and beekeeping does not compete with other agricultural activities. Indeed it can greatly enrich them, through the bees' pollination of crops. □

Boats from the past

A Symposium on Boat Archaeology was held at the National Maritime Museum on September 20-24, 1976.

from Lynette Hamblin

BOATS and ships are among the largest and most complex movable structures attempted by man throughout his history, and as such offer much insight into his technical capability and organisation throughout the ages. Boat archaeology, however, is still in its adolescence and the symposium brought together nearly 100 international experts to discuss a number of the basic disciplines relevant to this specialised branch of archaeology. Techniques for recording finds and

presenting information, the problems of building boat replicas, hypothetical reconstructions of boat finds and ancient boatbuilding methods were all covered.

In-depth field recording is essential in any archaeological excavation, particularly in the case of wreck sites underwater, where material which has been perfectly preserved is prone to rapid destruction once on dry land. Whereas objects can be lifted and preserved without overwhelming difficulty, the timber of a ship presents a different problem. Lifting any boat can overstrain the conservation resources of a national museum and, unless special units can be set up to deal with specific craft, it is impracticable to haul hundreds of feet of waterlogged timber out of their protecting environment into an atmosphere where they will quickly twist, warp and ultimately disintegrate if not treated. The great ship of the Egyptian Pharaoh Cheops was preserved for 4,500 years in a bone dry, hermetically sealed pit; in the mere six years since it has been excavated and reconstructed condensation and lack of climatic stability has set up drastic deterioration. The air conditioning in the glass-walled museum that houses it is inadequate and the stress on the rebuilt timbers is proving critical.

As naval architect J. F. Coates pointed out boat reconstructions present many problems. Very often a boat find consists of only the bottom of the hull and one, if not both, ends may be missing too.

The Bronze Age boats found at North Ferriby present reconstructors with many puzzles. Nearly all the main pieces forming the bottom, and a bit of one end of a lower side strake were found; these were massive pieces of hewn oak sewn together with yew twig stitches. Coates described three possible reconstructions based on this material. The first was an effort to design a boat with the smallest amount of extra material in it. Such a boat could ferry ten people and eight paddlers across the Humber. The second reconstruction was a more ambitious and higher quality craft which could carry a larger load. However, strains increase with load and weight so design number two may be asking too much of its moss caulking—it would be necessary to find out how badly the boats leaked and this calls for a replica. His third reconstruction moved away from the actual remains. He combined the very heavy oak pieces forming the lower shell with a much lighter skin construction for the upper parts. The adze marks on the North Ferriby boats are of the maximum size possible with the available tools in-

dicating that these boats could have been the Concordes of their time—"in proportion to the Gross Tribal Product they could have been as expensive but arguably more useful".

However, no matter how well a reconstruction is worked out by theory and applied knowledge no naval architect would be too confident of a boat's practical performance unless a replica had actually been made and tested at sea. The National Maritime Museum has pioneered this form of experimental archaeology in its practical research with a replica of the Gokstad *Faering*. Line drawing and a construction plan of the Oslo *faering* were published by A. E. Christensen in 1966 and these were of use in building the replica. However, it was only once the *faering* had been rebuilt and was undergoing sea trials that it was realised why the Oslo *faering* had such large holes in the forward *stammering*—the holes in the NMM *faering* were too small for a man's hand making it difficult to haul the boat up the beach.

Experimental archaeology is concerned with the processes and production methods used in the past, and with the function of the artefact. The reconstruction of an ocean-going skin boat, the Brendan exemplifies the many factors that need to be considered. This type of boat may have been used in the west of Ireland between the 5th and 9th centuries AD. Evidence for their design was gathered from references to skin boats in contemporary texts, ethnographic evidence of the skin boats descendants, surviving examples of leather boats (all river craft), materials research as well as research into the contemporary techniques available for leather and timber working.

With the help of the British Leather Manufacturers' Research Association a test programme was conducted into the properties of various leathers. It was found that by far the most suitable leather for the hull covering was the mediaeval type of leather, tanned in oak bark. A naval architect produced the plans for the replica and shipwrights were asked to fair up a wooden frame to these drawings. Only timber available in Ireland in the early Christian era was used. oak for the gunwales and thwarts, ash for the frames and stringers. The frame was lashed together using alum-tanned leather—a technique known in Roman times—and the entire structure was coated with wool grease to preserve the ash frame and protect the leather. Forty-two ox hides were needed to cover the boat, stitched together with hand-rolled flax. The Brendan has now successfully sailed to Greenland where it will have to spend the winter before completing the trip to North America.

Implications of pollen assemblage from the Koobi Fora Formation, East Rudolf, Kenya

Raymonde Bonnefille

Laboratoire de Géologie du Quaternaire, CNRS, 92190, Meudon-Bellevue, France

A pollen spectrum obtained from the Ileret Member of the Koobi Fora Formation indicates that vegetation patterns differed significantly from those prevailing east of Lake Rudolf today. The pollen-bearing sediment, which is interstratified with Plio-Pleistocene hominid fossils, shows somewhat more humid conditions.

PLIO-PLEISTOCENE lacustrine and fluvial strata exposed along the eastern side of Lake Turkana (Rudolf), Kenya are notable for their rich assemblages of fossil vertebrates¹, hominid remains² and early artefacts³. The geology and stratigraphy have been described by various authors who have worked in this area since 1969 (see refs 4-6).

Preliminary samplings for pollen analysis were taken at different localities where outcrops of the Koobi Fora Formation are exposed. Of the 27 samples, collected and examined, only one yielded pollen in sufficient quantity to justify study and interpretation. The pollen assemblage, Koobi Fora Formation Pollen Spectrum No. 1 (KFFP 1), was extracted from sandstone 3 m above the hominid site KNMER 1592 at Ileret, area 12 (Fig. 1). It comes from a stratigraphic level situated between the KBS Tuff and the Lower/Middle tuff complex. Two different sets of dates have been proposed for the KBS Tuff, one⁷ assigning it an age of 2.6 ± 0.26 Myr and the other assigning⁸ an age of 1.6 ± 0.05 Myr to the Upper KBS Tuff and 1.82 ± 0.04 Myr to the lower tuff.

The Ileret Lower/Middle Tuff complex has been dated⁹ at 1.48 ± 0.17 Myr. The pollen sample comes from just above the level which is interpreted equivalent in time to the post erosion surface (I. Findlater, personal communication) at an horizon that shows reverse polarity in other sections. From this it follows that if the first hypothesis is correct, the stratigraphical level from which the pollen assemblage was extracted would be dated between 1.8 and 2.4 Myr. For the time being it seems reasonable to treat the age of the pollen assemblage as being $\sim 1.5-1.6$ Myr.

Pollen extraction was undertaken on a 100-g sample of sediment after a positive result had been obtained with a 20-g sample. The chemical process involves first an attack with a 10% solution of HCl, dissolving the silicates with a 70% solution of HF, and subsequent density separation of the organic matter using 'Liqueur de Thoulet'. All the residue has been observed. The total count of pollen (696) represents the absolute quantity recorded in 100 g of sediment. No heavily corroded pollen grains were noticed.

Palynological results

Details of the pollen assemblage are given in Table 1. Identifications of pollen grains are based on a reference

slide collection which contains $\sim 4,000$ East African species. Morphological studies of > 350 species from the Omo area including light and scanning electron microscopic observations were also used. As can be seen in Table 1, some taxa have been identified at the family level, others at the generic or specific level.

Fig. 1 Map of the East Rudolph region, showing the sampling areas.

Taxonomic identifications

Taxa identified as Gramineae, Cyperaceae, Compositae, Liliaceae, Caryophyllaceae belong to botanical families in which pollen grains are very homogeneous. Pollens of grasses are porate, with one pore and a smooth exine. They offer very few characteristics which could be used for generic diagnosis. In the fossil pollen assemblage, grasses are very abundant, representing 43.5% of the total count. This percentage includes grasses growing near the lake shores or river banks as well as grasses in the savanna which cannot be distinguished on the basis of diameter measurements. Other taxa identified as Ericaceae, Acanthaceae, Liliaceae represent fossil pollen grains in which some details are not preserved, preventing identification beyond the family level.

Generic and specific identifications of the Amaranth pollen grains are based on recent work by Rioulet and Bonnefille⁹. Of the genus *Olea*, six species are known in the East African flora. Two separate pollen types can be distinguished, the type *O. africana* (= *O. chrysophylla*) in which the exine shows a reticulum with large lumina and the type *O. hochstetteri* which has smaller lumina.

In Table 1, specific identifications are given for pollens recognisable by morphological details, which belong to contemporary African genera only known through a single species. These are *Dodonaea viscosa*, *Hagenia abyssinica* and *Ricinus communis*. Within other genera such as *Justicia*, certain species show strong differences. Pollen grains of *Justicia anselliana* are small (~20 µm) and diporate. They have no furrows visible and the exine is of about the

same thickness at the pore and at the equator. *Justicia odora* and *Justicia fischeri* pollen grains are dicolporate with a long visible furrow, their size is $\sim 35 \mu\text{m}$. They cannot be distinguished from each other, and so the fossil has been designated as *Justicia* cf. *odora* type. But this pollen is very different from *J. flava* or *J. striata* which show a very strong thickening of the exine at the equator.

Pollen grains classified under species A are represented by periporate grains of $\sim 20 \mu\text{m}$ with 12 to 15 pores. The pores are well-delimited with an operculum. On the optical sections very fine columellae are barely seen. Such pollen exist among Plantaginaceae (*Plantago*) and Moraceae (*Bosqueia*). Considering the exine structure and the pores, the fossil pollen grains closely resemble those of *Bosqueia phoberos* (= *B. angolensis*) a common tree of the most humid high forest of western Ethiopia and of the rain forest in the Congo. The regular undulations with the verrucate or microechinate sculpturing which characterise the exine of pollen grains in the genus *Plantago* have not been clearly observed on the fossil pollen. In the present East African species of *Plantago*, the pore outline is not well delimited and the pore membrane is covered with granules. No distinct operculum is visible, except in *P. lanceolata*. But in this species, the exine is echinate. The fossil pollen grains cannot be attributed to the genus *Plantago*. They are considered to be close to *Bosqueia*. The possibility that they could belong to an extinct species cannot, however, be excluded.

Pollen grains of species B are tricolporate with granulate colpi membranes, a smooth exine surface and no distinct columella. Similar pollen exists within the 'Meliaceae' family. The fossils, however, are not identical to the living African species of Meliaceae which we have observed.

Pollen grains similar to species A or B have never been recovered from the modern pollen rain content of the East Rudolf or Omo areas. Whatever their precise identification, they have to be included in group A of Table 1.

Comments on the fossil pollen assemblage

Within the fossil pollen assemblage the different taxa have been arranged in five groups (Table 1).

The first group consists of taxa which are not represented today in the vegetation of the East Rudolf area according to the lists established on the basis of the collections of plants made by many authors. This first group has been divided into two parts, A and B. A includes taxa from montane forests of the Ethiopian highlands and B taxa from riverine plant communities. In the second group are

considered taxa from the surrounding semi-desert steppes of the Lake Turkana area. Within a third group are assembled ubiquitous taxa among which grasses are particularly abundant.

As we cannot distinguish the different genera of grasses which belong to distinct communities, we must consider them as a whole. *Typha* is usually found near fresh water but Cyperaceae (sedges), which can be very abundant near saline or alkaline lakes, do exist within savannas among other herbaceous plants. Compositae of the tubuliflorae type as well as Acanthaceae have been classified as ubiquitous taxa because of the imprecise nature of their identification. The fourth and fifth groups are respectively represented by the pteridophyte spores and the unidentifiable pollen.

The survey of the fossil pollen assemblage (Table 1) shows that among the 47 pollen taxa recorded (pteridophytes included), more than half of them, that is 25 (group 1), are not present in the contemporary East Rudolf vegetation. Nine of them may occur in riverine communities along the Omo river and in the delta, north of Lake Turkana. The other 16 exist, now, in the high forests of south-western Ethiopia, in the Gemu-Gofa and Sidamo provinces, 150 to 200 km east or north of Meret. The great number of taxa which are not represented in the vegetation of the East Rudolf area today seem to be a remarkable feature of this fossil pollen assemblage.

Comparison with palynological results from modern sediments

Samples of recent sediments were collected as a part of A. K. Behrensmeyer's research into taphonomy. They were taken from lake margin environments at Alia Bay and from modern fluvial ones at the Laga Bura Hasuma and Tulu Bor, both of which are seasonal water courses (Fig. 1).

Table 2 summarises the percentages of pollen of the previously defined groups in these samples, detailed counts will be found in another paper¹¹. For the palynological data obtained from recent sediments, pollens which belong to taxa from montane and forest communities are considered as allochthonous, that is, transported from the source to the place of deposition. Allochthonous pollen give information on the vegetation of the whole basin.

Implications for regional vegetation patterns

In all the studied samples from recent sediments, the percentages of allochthonous pollen are very small (0.04–2% of

the total count, or 0.5-4.8% of the total from which grasses are excluded). There are slight differences between the percentages of lacustrine and fluvial allochthonous taxa observed in the various samples. (Table 2).

By contrast the number of riverine and highland taxa is much more important in the fossil assemblage than in any recent samples (Table 3). Altogether the percentages of those taxa represent 16.2% of the total pollen (Table 1) or 28.7% of the total pollen after Gramineae are excluded (Table 4). Such large percentages of highland taxa have been recorded in a pollen spectrum of recent Omo river deposits only from a site 50 km North of the Omo delta and 150 km north of Ileret (Table 4). In this recent assemblage, allochthonous pollen from the Ethiopian highlands is brought down streams.

Considering the fossil data, there seem to be three principle lines of explanation for the higher percentages of allochthonous pollen compared with recent spectra: first, the allochthonous pollen may formerly have been introduced from the north-east by a large river which has now ceased to flow; second, the incidence of allochthonous pollen in recent sediments may have been artificially depressed by recent deforestation caused by human interference, and third, at the time of the deposition of the fossil sample, different environmental conditions may have permitted the growth of montane forest species closer to Ileret than today.

The first seems unlikely through a detailed reconstruction of the palaeogeography¹¹. Also bones and hominid remains, particularly abundant in area 12, have not been subjected to noticeable reworking. Modern sediments from the delta margin transect of Alia Bay are considered by Behrensmeyer as the closest model for deposition of the Lower Pleistocene sediments at Ileret. On the basis of the geological data, stream transport of pollen seems an unlikely explanation of the high value of mountain taxa in the fossil pollen assemblage. Furthermore, if the fossil pollen assemblage at East Rudolf was from a fluvial environment, it should also show a higher concentration of riverine taxa than are in fact recorded (compare data for recent sediments of the Omo River, Table 4). No pollen of *Zyzygium*, *Celtis* or *Ziziphus*, all common trees of riverine plant communities, have been recorded in this sample. Even if a part of the allochthonous fossil pollen was introduced by fluvial transport, it should be noted that the modern rivers on the eastern side of Lake Turkana do not transport comparable pollens. Also, the

whole picture given by the pollen spectrum is consistent with deposition in a situation between the distributary channels of a delta.

For the second possible explanation, it is apparent that if the differences between recent and fossil assemblages are to be attributed to intensified human activity, then all early fossil assemblages from Omo and East Rudolf should differ from the modern ones in a similar manner. Tables 3 and 4 demonstrate the contrary. Strong fluctuations in the amounts of montane forest pollen have already been noticed in Plio-Pleistocene sediments of the Shungura Formation in the lower Omo Valley¹².

Explanations of the contrast between the fossil and recent spectra which depend purely on differences of environment of deposition seem highly unlikely in view of the recent demonstration that these do not greatly influence the relative quantity of allochthonous pollen¹³. I therefore favour the third explanation, namely that the fossil sample reflects climatic and ecological environmental conditions differing significantly from those of the present day. At Ileret, 1.5 Myr ago, climatic conditions must have been cooler and more humid than today, and more favourable to extensive forests.

Implications for local vegetation patterns

In the fossil pollen assemblage from Ileret (Table 1) group 2, which contains the taxa recorded today in the East Rudolf vegetation, shows a great abundance of *Acacia*+*Capparaeae*+*Commiphora* and *Salvadoraceae*, all common trees of the dry woodland. Among the herbaceous taxa, *Chenopodiaceae*+*Amaranthaceae* are the most abundant, with the *Euphorbiaceae*. No interpretation can be made of the *Euphorbia* pollen since ~ 100 species with different ecologies are found in East Africa. It is not the *Euphorbia grandicornis* commonly found in this subdesert area.

Chenopodiaceae and Amaranthaceae

Among the *Chenopodiaceae* it was not possible to increase the precision of pollen identification to the generic level. The fossil pollens are very similar to pollens of *Suaeda* or *Fadenia*, very abundant today in the vegetation surrounding Lake Turkana. Altogether *Chenopodiaceae* + *Gramineae* + *Amaranthaceae* + *Cyperaceae* represent ~ 60% of the fossil pollen count. The recent lacustrine samples from East Rudolf are extremely consistent with high values

Table 4 Comparative pollen composition (as percentages) of Plio-Pleistocene deposits against modern surface sediments from Omo and East Rudolf

% expressed as percentages of total count excluding Gramineae and over-represented species.

of Chenopodiaceae associated with Cyperaceae and Gramineae (97–99%) while the fluviatile series are more variable (62–96%).

Pollen analyses of surface sediment samples have shown high percentages of Chenopodiaceae in the subdesert and desert areas of the Sahara^{13,14}, in the arid zones of the Middle East, in Iran¹⁵, and also in the southwestern USA (such as Arizona¹⁶) as well as in dry continental areas of the USSR¹⁷. Chenopodiaceae are numerous in places with high salinity or alkaline soils.

On the basis of modern pollen rain studies, authors agree that high values of Chenopodiaceae pollen are obtained near places where the plants are found. Their density decreases rapidly with distance from the source. For this reason, high Chenopodiaceae frequencies in fossil data are basically the result of local conditions rather than regional ones. In this particular fossil assemblage, related to a delta margin environment, a percentage of Chenopodiaceae much lower than in the recent Alia Bay samples may indicate a lake less alkaline than the present one.

Woodland and bushland

Percentage calculations of the various savanna taxa included in the groups 2+3 (Table 1) of the fossil pollen assemblage are given in Table 5. They provide information on the composition of the local vegetation around Lake Turkana in the past. It should be noticed that the pollen composition of the fossil assemblage differs from all the studied modern spectra in containing a great quantity of *Acacia* and *Commiphora*. The ratio between arborescent and non-arborescent taxa calculated from Table 5 has about the same values as for recent pollen spectra from surface samples collected beneath tree cover near the Tulu Bor River, east of Lake Turkana¹⁹. We consider that the vegetation near the lake at the time of deposition of the sediment, was more wooded than today, and can be regarded as *Acacia-Commiphora* bushland. The great percentage of pollen of Salvadoraceae, in which the identification of *Salvadora* from *Dobera* is not possible, could reflect the mesic environment near a river delta.

Discussion

Because of the present lack of data on the pollen rain in tropical lowlands, great caution is needed in the palaeoclimatic interpretation of this pollen analysis. A pollen assemblage does not exactly reproduce the detailed composition of the regional vegetation, but it reflects the essential character of the flora which existed at the time of deposition. Such information on vegetation would not be available without palynological studies.

The composition of the plant community and the resultant pollen rain can be related by correlation factors to allow for the differential pollen production by wind-pollinated and insect-pollinated plants. For the moment no great precision is possible. But we have, in effect, taken those factors into account by comparing the fossil assemblage with assemblages of recent pollen deposited in the same area. More sophisticated treatment must await the compilation of much more comparative data on pollen production, absolute and relative dispersal in such tropical areas. In spite of the reservations just expressed, it remains true that plants constitute the most sensitive indicators of climatic, hydrological and pedological conditions of their habitat. The ecological requirements for certain species and vegetation communities are so precise that they can be used to characterise particular climatic regimes.

The fossil pollen assemblage from Ileret seems to permit a reasonably definite characterisation of the flora in the area, 1.5 Myr ago. The prominence of montane forest elements is particularly striking. Since it appears that this feature cannot be explained entirely by long distance wind or water transport, it seems clear that vegetation of highland forest type must have existed closer to the basin

Table 5 Distribution of savanna taxa (groups 2+3 of table 1) in the fossil pollen spectrum KFFPI

† With Chenopodiaceae + Cyperaceae + *Typha* Gramineae excluded. Pollen sum 130.

margins. Further, because the contrast between recent pollen assemblages and the fossil one cannot have arisen simply from recent deforestation, the climate must surely have been somewhat cooler or wetter at the time of deposition of the sample. The vegetation in the vicinity of the sample site was dominated by Gramineae and Chenopodiaceae appropriate to the margins of a slightly saline or alkaline lake. On the other hand, the unusually good representation of *Acacia*, *Commiphora* and *Salvadora* implies a shrub and tree cover that was more dense than that prevalent in the basin today. Altogether the indications are of a climate that was neither excessively humid nor semi-arid.

The sample was taken from strata which contain early hominid fossils and archaeological remains of the Upper Member of the Koobi Fora Formation. The pollen spectrum of the Koobi Fora documents conditions existing at some point during the occupation of the area by evolving hominid populations. The palaeoenvironmental evidence provided by this sample, however, refers to a relatively short timespan during the deposition of the sediment containing the pollen spectrum. To assess the extent to which the pattern observed was stable, fluctuating or subject to persistent long term trends, we will need to procure spectra from other layers.

I thank Glynn Isaac and Richard Leakey for help, and the CNRS and the NSF for support. A. K. Behrensmeyer, G. Isaac and I. Findlater helped with the field work, with stratigraphic interpretation and in the preparation of the report. J. B. Gillett and C. Kabuye provided botanical specimens from the East African Herbarium, Nairobi. C. Vanbesien and G. Buchet gave assistance in the laboratory.

Wind shear observations in thunderstorm density currents

F. F. Hall, Jr & W. D. Neff

Wave Propagation Laboratory, National Oceanic & Atmospheric Administration, Environmental Research Laboratories, Boulder, Colorado 80302

T. V. Frazier

Department of Physics, University of Nevada, Reno, Nevada 89507

Acoustic sounder observations of thunderstorm density currents reveal a complicated but ordered internal structure. Fast-response anemometers on a 150-m tower reveal a succession of internal shear layers which occur following the leading portion or nose of the current. The measured wind shear revealed by the anemometers is found to be a function of the temperature differential between the ambient air and the interior of the gust, measured near the surface. An heuristic model is developed to explain this observation.

DENSITY currents flowing out from thunderstorms, sometimes referred to as gust fronts or microfronts, can constitute a hazard to the landing and takeoff of aircraft. The associated wind shear results in the aircraft experiencing rapid changes in air speed; vertical shears $> 0.1 \text{ s}^{-1}$ in the lowest 100 m have been shown to be hazardous to large, swept-wing, jet-powered aircraft in a study by Snyder¹. An improved knowledge of density current dynamics and structure is also important in understanding the interaction of the thunderstorm with its environment. Since the cold air outflows from storms are statically stable, but highly turbulent, such currents exhibit large acoustic index of refraction fluctuations, leading to strong acoustic echoes when the flows are probed with sound waves. Using an acoustic sounder as a guide in the interpretation of meteorological tower data we present new observations of the internal structure and shear in gust fronts, and find a strong correlation between the strength of the current and its temperature contrast with the ambient air.

Wind shear measurements

During field experiments in 1972 and 1974, five different thunderstorm density currents were observed at the National

Oceanic and Atmospheric Administration (NOAA), Haswell, Colorado site. The meteorological tower at Haswell, 150 m tall and located 300 m from an acoustic sounder, was instrumented at 30-m intervals with fast response wind and temperature sensors; data were recorded at 1.0-s intervals. In addition, heavy-duty wind sensors were located at 15 m and 150 m, and were able to withstand the high winds which in two cases destroyed the fast response instruments.

In the two more severe storms observed, wind-generated noise at the acoustic antenna masked the reception of echoes, but for the other cases, the internal shear structure was observed in detail with the sounder. The structure for the August 11, 1972 current is shown in Fig. 1. This outflow originated near a line of small thunderstorms which had levelled off at a peak altitude of 8.5 km above sea level, and were observed to dissipate 20 km NE of Haswell at 2300 by the National Weather Service weather radar in Limon, Colorado. When last observed the storms were moving 6 m s^{-1} from an azimuth of 330° . The maximum wind speeds within the current were 5 m s^{-1} from between 280° and 340° . This density current flow was opposed to an ambient flow of 10 m s^{-1} from 135° before the event, producing a vector change in wind speed, Δu of 15 m s^{-1} . A temperature drop of 2°C at 30 m occurred with the passage of the microfront or head of the current. Maximum shears at the lower edge and in the interior of the current reached values of $\partial u / \partial z = 0.13 \text{ s}^{-1}$ as measured by the tower bivanies; the strongest shear events correlated with temperature shifts measured on the tower and with the observation of scattering regions on the acoustic sounder facsimile record. This correlation is to be expected since theory predicts that the acoustic scattering is produced by small scale temperature fluctuations associated with turbulence in regions of temperature and wind gradients.

This prediction has been verified quantitatively by Neff² for a number of cases including elevated scattering layers. The

Fig. 1 Acoustic sounder facsimile record obtained on August 11, 1972 at Haswell, Colorado, of a density current originating from a line of weak storms more than 20 km away. Wind noise associated with the passage of the current nose led to the vertical noise-lines in the upper part of the record at 2320. The postulated shears and temperature gradients at the edge of the current, and in descending layers within the current, are revealed as darker regions on the facsimile record because of increased acoustic scattering cross sections.

Fig. 2 Isotachs in m s^{-1} drawn against height and time as derived from wind measurements at six levels on the Haswell tower, 10-s averaged data for the density current of August 5, 1972. The resulting pattern of shear is consistent with the layered structure shown by acoustic sounder observations of much weaker currents as in Fig. 1.

thin, tilted echo layers, internal to the current but above the height of the tower, are thus presumably of such an origin. Although not verifiable from the present data, the local enhancement of the shear and consequent production of turbulence may arise from internal waves generated at the interface or large-scale overturning within the current.

Two more vigorous density currents from closer and larger thunderstorms passed the tower on August 2 and 5, 1972. In these cases, the wind noise was so great that acoustic records could not be obtained. By using the August 11 facsimile record as a guide in interpreting the wind data from the tower, however, a consistent set of isotachs could be plotted for the August 5 event following the form suggested by Fig. 1, with tilted shear layers gradually sloping or descending with time. These are shown in Fig. 2, plotted from data averaged over 10 s. One minute of data averaging proved to be too long to delineate the thin shear regions within the currents; therefore, internal shear layers were not revealed in the recent comprehensive thunderstorm outflow study by Goff⁴, who used 2-min wind averages.

From Fig. 2, it is immediately obvious that the vertical shear $\partial u / \partial z$ in the lower 50 m is consistently large and above the aircraft safety criterion set by Snyder¹. It must be realised that the spatial slope of the higher shear zones is greatly accentuated in Figs 1 and 2; if one assumes the zones are advected with the mean wind, the actual slopes for the shear

regions at 100 m are found to be $< 2^\circ$. The fluctuating nature of the shear at higher levels yields an undulatory pattern of shears $> 0.1 \text{ s}^{-1}$. Regions where this critical shear value is exceeded are shown in Fig. 3, indicating that even 16 km from this quite averagely sized prairie thunderstorm (with radar echoes extending to an altitude of 14.6 km), the clear air wind shear exceeded the safety limits consistently in the lower 100 m for > 10 min. Shortly after 1946 on August 5, a gust of more than 25 m s^{-1} destroyed two of the light weight propellers on the fast response sensors, or bivanes, eliminating further data.

The even more energetic density current of August 2, 1972 arose from a storm just 5 km away with radar tops observed to be above 17 km. Maximum velocities in this current exceeded 42 m s^{-1} , which quickly destroyed all bivanes on the tower. A recorded wind shear of 0.26 s^{-1} was observed over the 135-m separation of the two more rugged but slower response wind sensors. Thus the actual shear internal to the current (which otherwise might have been measured with 30-m height resolution provided by the bivanes) was probably greater than that recorded over the greater height increment separating the rugged sensors.

A model of density current wind shear

A feature common to the density current events observed was the drop in temperature with the arrival of the first gust. Empirically, it was found that the larger the temperature drop,

Fig. 3 Height against time plot of those regions where the wind shear exceeded 0.1 s^{-1} for the August 5, 1972 density current at Haswell, Colorado.

the greater the observed shear, consistent with the primitive equation model of gust fronts by Mitchell⁵. This suggested that temperature measurements relatively near the surface might serve as a quantitative predictor of the severity of density current shears. We now outline a simple model relating temperature drop to wind shear.

An obviously relevant parameter in density current modelling is the speed of the current, u_s . This is given by Turner⁶ as

$$u_s = \alpha [gH(T_a - T_g)/T_a]^{1/2} \quad (1)$$

where g is the acceleration of gravity, H is the depth of the current following the head, T_a the ambient air temperature, and T_g the temperature of the gust. Equation (1) comes from hydraulic theory. When dissipative processes are neglected the constant, α , is $\sqrt{2}$. Laboratory investigations yield an empirical value for α of 1.1 (ref. 3).

We consider first the shear along the upper boundary of the current near its nose. In this region of warm air overlying the colder current, we hypothesise that the turbulence generated there self-adjusts to gradient Richardson numbers, Ri (~ 0.2), as observed in thin inversion surfaces in the real atmosphere (Turner⁶, Hall *et al.*⁷). From the definition of Ri we write

$$\frac{\partial u}{\partial z} = \frac{1}{Ri} \frac{g}{\theta} \frac{\partial \theta}{\partial z} \quad (2)$$

This can be approximated as

$$\frac{\partial u}{\partial z} \approx \frac{1}{Ri} \frac{g}{T} \frac{\Delta T}{\Delta u} \quad (3)$$

where the vertical gradients are assumed to occur over the same depths, the temperature lapse rates within and outside of the current are nearly equal, and $\Delta T = T_a - T_g$, measured near the surface. Assuming the ambient flow velocity is zero, $\Delta u = u_s$. Then equation (3) becomes

$$\frac{\partial u}{\partial z} = \frac{1}{\alpha Ri} \left(\frac{g \Delta T}{HT} \right)^{1/2} \quad (4)$$

Fig. 4 Measured wind shear plotted against temperature drop from the ambient atmosphere to the density current. The experimental data points, as described in the text, nearly fit a straight line, while the overlay stippled area represents approximate bounds on the shear predicted by equation (7).

Taking $H = 500$ m, which the sounder reveals to be a characteristic value for a number of such currents observed, $Ri = 0.2$, $\alpha = 1.1$ and $T = 300$ K, we have

$$\frac{\partial u}{\partial z} = 0.037(\Delta T)^{1/2} \quad (5)$$

For $\Delta T > 7^\circ\text{C}$ at the upper boundary of the current, equation (5) predicts wind shears > 0.1 , the safety limit derived by Snyder¹.

At the lower boundary of the current, where the shear is actually measurable on the tower, the speed must go to zero through some boundary layer thickness δ . We can then use equation (1) to estimate

$$\frac{\partial u}{\partial z} = \frac{u_s}{\delta} = \alpha \left(\frac{gH\Delta T}{\delta^2 T} \right)^{1/2} \quad (6)$$

Taking again $H \approx 500$ m and $50 \text{ m} < \delta < 100$ m (typically observed values) we have

$$0.044(\Delta T)^{1/2} < \frac{\partial u}{\partial z} < 0.089(\Delta T)^{1/2} \quad (7)$$

expressions surprisingly similar to equation (5), but predicting shears near the surface somewhat larger than at the upper boundary of the current.

A summary of the maximum observed wind shear for five density currents as recorded at Haswell is shown in Fig. 4, where the dated data points show the values recorded by bivanes on the 150-m tower, except for the August 2, 1972 event. Other points shown were recorded by Charba⁸ and by Marks⁹ at the WKY tower near Oklahoma City. The Goldman and Sloss¹⁰ data were obtained at the 150-m Kennedy Space Center, Florida tower. A least-squares linear fit to the data, relating wind shear to temperature drop observed in the density current, is shown as a solid line. The equation for this line is

$$\frac{\partial u}{\partial z} = 0.024 \Delta T + 0.03 \quad (8)$$

The area bounded by the limits of equation (7) is plotted as the stippled overlay which agrees well with the data. Equation (5) would plot near the lower bound of the stippled zone. The non-zero intercept in Fig. 4 probably reflects our neglect of the background shear.

The fact that the observed shear varies nearly linearly with ΔT may reflect an indirect dependence of H on ΔT as suggested in the two-dimensional primitive equation model of Mitchell⁵. Our simple heuristic model also avoids the variability in the static stability of the ambient air. Equation (7) is thus useful mainly to set approximate bounds on the shear using values of H typical of the few cases observed by the sounder.

If the simple relationships shown in Fig. 4 prove to be typical for an even larger data set, it would be a relatively simple matter to measure ΔT on a grid surrounding airports to warn of the wind shear produced by density currents moving across the area.

Conclusions

We conclude that even at distances > 16 km from thunderstorms, the wind shear in density currents from such storms can be a hazard to aircraft landing and taking off. Unless such density currents are delineated by blown dust, as in desert regions, they will be undetectable to the unaided observer. The temperature drop associated with these currents, however, gives a good measure of the wind shear to be expected. In addition, the ability of the acoustic sounder to detect such turbulent shear layers may provide new insight into the internal dynamics and structure of such currents in the atmosphere.

We thank D. W. Beran, W. H. Hooke, C. G. Little and P. A. Mandics for discussions. G. Gertig assisted with the data reduction and the plotting. Support for this study was provided by the Federal Aviation Administration.

Cell surface distribution of lectin receptors determined by resonance energy transfer

S. M. Fernandez & R. D. Berlin

Department of Physiology, University of Connecticut Health Center, Farmington, Connecticut 06032

The surface topography of concanavalin A (con A) bound to normal and transformed murine fibroblasts has been studied by a new technique involving fluorescence resonance energy transfer (RET). RET can provide a high resolution "map" of the distances separating con A-receptor complexes in single living cells. The distribution of con A is non-random in both normal and transformed cells, but sites are more closely approximated in the transformed. Approximation is induced by the con A but occurs at extremely slow rates indicating that the topography is not primarily determined by simple diffusion of complexes.

THE enhanced agglutinability of tumour compared with normal cells by plant lectins such as concanavalin A (con A) has led to the extensive use of lectins as "probes" of surface organisation. Yet the essential description of the binding of lectins to cell surfaces is controversial and incomplete. Although the number of binding sites per cell is equal^{1,2}, the surface density of bound con A is probably greater on transformed than normal cultured fibroblasts³. The distribution of con A over the surface may also be markedly different. The aggregation of con A-receptor complexes (C-R complexes) into clusters has been considered characteristic of the malignant cell⁴. The formation of these clusters depends on the movement of C-R complexes. When cells are prefixed with aldehydes and then labelled, the distribution of C-R complexes appears disperse or "random" on transformed as well as normal fibroblasts⁵. Thus C-R complexes are said to be more "mobile" on transformed cells. Similarly, after colchicine treatment, bound con A is distributed in large aggregates or caps on transformed but not on normal cultured fibroblasts⁶. These differences have been attributed alternatively to the intrinsic fluidity of the membrane or to submembranous structures, such as microtubules, which can modify the topography and apparent mobility of C-R complexes.

In our view, the available methodology has had two major limitations. First, the degree of topographical order has been difficult to quantify from electron micrographs. The terms "random", "dispersed" or "clustered" used to characterise the surface distribution of C-R complexes are not defined. Only marked degrees of clustering are obvious and subtle changes in topography cannot be determined. The assessment of order is further complicated by problems of statistical sampling of cells or regions of their surfaces.

Second, the distribution of C-R complexes on living cells has been studied only by fluorescence microscopy. This technique

permits direct observation of gross changes in C-R distribution ("random", large aggregates or caps) but does not allow observations at high resolution in dynamic conditions. Thus, the history of a given topographical distribution as seen on surface replicas by electron microscopy can only be reconstructed indirectly.

We describe here an approach to the analysis of surface topography that obviates some of these problems. We have utilised fluorescence resonance energy transfer (RET) between molecules of surface-bound con A to measure the distances separating them. The method makes possible the development of a high resolution "map" of the topography of C-R complexes. We have analysed the topography of C-R complexes on normal and transformed fibroblasts. The results provide a quantitative description of differences in the topographical organisation of C-R complexes between normal and transformed cells. The time course over which some of these differences evolve is very long and seems to exclude the rate of receptor diffusion as a major determinant of topographical organisation.

High resolution topographical mapping by RET

RET occurs when a donor chromophore which is excited by the absorption of light transmits some of the absorbed energy to another (acceptor) chromophore some distance away. This transfer does not involve the actual reabsorption of light by the acceptor but requires that the distance between the chromophores be relatively close (usually not exceeding 100 Å). Energy transfer varies most importantly as the inverse of the sixth power of the distance separating the chromophores. From the extent of transfer, quantitative theory allows an estimate of the distance between chromophores⁷. By labelling subpopulations of microtubule subunits or membranes with different chromophores, we have used the technique for the study of microtubule polymerisation and membrane-microtubule interaction *in vitro*⁸.

In the study reported here the con A used for cell labelling was a mixture of two populations separately conjugated to donor or acceptor fluorochromes. The ratio of acceptor to donor and the absolute dye to protein ratios were chosen such that at the surface density of bound con A an approximation of C-R complexes would be observed as an increase in RET.

Our system has two characteristics not frequently encountered in recent applications of RET. First, in our system the distance between donor and acceptor is not fixed. The chromophores are not placed at different sites on the same molecule as they are in applications in which RET can be used as a "spectroscopic ruler"⁹. Instead, because the chromophores are placed on different molecules statistically distributed over the two-

Fig. 1 Modified Zeiss microscope equipped for epiillumination. The incident light source was a Photophysics nanosecond flash lamp. The source was focused through a UG1 filter on to a Zeiss No. 450 dichroic mirror. Light was reflected downward and focussed on to the sample through the microscope objective (usually a planachromat 1.25 NA \times 100). Specimen fluorescence was collected in the objective, passed through the mirror, focussed on a grating monochromator and thence to a RCA 8850 photomultiplier. A monophoton counting device was used to record the light incident on the photomultiplier. A detailed description of the apparatus will be given separately (S.M.F., in preparation).

dimensional cell surface, the distance between chromophores varies in a corresponding statistical manner. An increase in RET thus corresponds to a statistical packing or aggregation of donors and acceptors. The analysis of this situation is not novel. RET between mixtures of chromophores in solution was the first system to be analysed by Förster⁷ and other physical chemists (for example, ref. 10). Second, in our analysis only changes in RET are considered useful. It has been emphasised repeatedly that the precise calculation of distances between donors and acceptors based on RET depends on the orientation and mobility of absorption and emission dipoles¹¹. This information is rarely available. We assume only that the orientation factors remain essentially constant throughout our experiment and focus attention on temporal variations of RET. Changes in RET represent changes in the distance separating donors and acceptors. We emphasise, however, that these relative distances correspond to changes of only a few Ångströms, for no energy transfer is detectable at separations exceeding 100 Å.

Observations were made with a modified fluorescence microscope using reflected light (epiillumination). This method of illumination provided sufficient intensity at the specimen when weak light sources (such as a flash lamp) were used. Fluorescence was detected using a sensitive monophoton counting device. The apparatus is shown in Fig. 1.

The ratio of acceptor to donor chromophores in mixtures used to label cells has proved critical. A model system in which this ratio is varied experimentally and related to the RET illustrates the principle and reveals several other features of our rationale. For these experiments, we used tubulin (tubulin and con A are approximately equal in molecular weight) which was

available in bulk and could be labelled conveniently to various ratios of dye to protein. We prepared mixtures of tubulin separately labelled with dimethylamino-naphthalene sulphonylchloride (DANS) or rhodamine isothiocyanate (RITC), and added various amounts of unlabelled tubulin. The proteins were cross linked with glutaraldehyde, concentrated and smeared on to glass slides for examination of fluorescence in our instrument. The precise calculation of RET from donor and acceptor fluorescence is a useful method for analysis of solutions and has been detailed elsewhere¹². Information on absorption by donor and acceptor and on acceptor quantum yield, however, is required and can be obtained only with great difficulty through the microscope. Since RET results in an increase in acceptor emission (sensitised fluorescence) and a decrease in donor fluorescence, we took the ratio of acceptor to donor fluorescence as an approximate measure of RET. This measure proved useful and, we feel, appropriate in view of our emphasis on relative changes and the uncertainties in obtaining less empirical expressions for RET. Figure 2 is a plot of the ratio of acceptor to donor fluorescence at different ratios of chromophores as a function of the mean distance between chromophores. As the distance increases, the ratio of fluorescence tends to a limiting value irrespective of the ratio of chromophores. This value is presumably characteristic of the shape of the donor fluorescence spectrum and any direct excitation of the acceptor and corresponds to the absence of RET. The existence of this limiting value enables one to set an empirical limit beyond which RET does not occur. Furthermore, the fluorescence ratio is more sensitive to changes in distance between fluorophores at high ratios of acceptor to donor. Thus for our experiments the ratio of acceptor to donor was set at about 5 to 1. Clearly at some still higher acceptor to donor ratio, RET from donor to acceptor will be essentially complete over a wide range of distances. Consequently RET gives poor resolution of donor to acceptor distances at both very low and very high ratios.

Fig. 2 Ratio of acceptor (rhodamine) to donor (DANS) fluorescence, I_R/I_D , in aggregated tubulin mixtures as a function of interfluorophore distance. The peak intensities at 570 nm and 515 nm were taken as a measure of acceptor and donor fluorescence, respectively. Tubulin was prepared by cyclic polymerisation by the method of Shelanski¹³ and labelled with DANS or RITC. Ratios of dye to protein were determined from the characteristic absorption at 350 nm and 553 nm, respectively, and protein by the method of Lowry¹⁴ using bovine serum albumin as standard. The separately labelled tubulin was mixed to give the desired acceptor to donor ratio and diluted with unlabelled tubulin in various amounts. The mixtures were then incubated with 20% glutaraldehyde in the cold overnight, precipitated with acetone and washed in media. The cross-linked precipitate was then smeared on a glass slide under a coverslip and examined in our instrument. The mean distance is calculated between all species of dyes taking each fluorophore as a point source and the density of the hydrated precipitate as 1.0.

Fig. 3 Ratio of acceptor (rhodamine) to donor (DANS) fluorescence, I_R/I_D , from con A-labelled murine fibroblasts as a function of time of incubation at room temperature. The ratio of rhodamine to DANS was 5 to 1, the ratios of dye to con A protein were 3.8 to 1 for DANS-con A and 7 to 1 for RITC-con A. Total con A labelling concentration was $180 \mu\text{g ml}^{-1}$. Cells were labelled at 4°C for 1 h as described and excess dye was removed. Observations on the microscope stage at room temperature were commenced immediately after removal of dye. Cells were located by phase contrast using green filtered light. The flash lamp used to excite the specimen did not bleach the dye. In fixed specimens identical readings could be obtained for hours. Thus, membrane or other damage which could result from the high light intensities associated with bleaching (that are obviously essential for the photobleaching technique)²⁴⁻²⁶ is minimised. Δ , SV3T3 cells; \bullet , 3T3 cells.

Surface topography of con A-labelled fibroblasts

The application of the technique to living 3T3 and SV40-transformed 3T3 fibroblasts is partly confirmatory of previous studies of con A surface topography: C-R complexes are more clustered on transformed than normal cells^{4,5}. In addition, several features of the dynamics of C-R interaction are revealed, and the distribution of C-R complexes on 3T3 is shown to be non-random.

Con A was labelled with DANS (as the cycloheptaamylose complex)¹⁶ or RITC and purified by affinity chromatography as previously described¹⁶. Fibroblasts were grown in modified Dulbecco's medium with 10% calf serum on glass coverslips. Monolayers were labelled with mixtures of DANS-con A and RITC-con A at 4°C for 1 h. After rinsing away excess dye, the coverslips (fixed or unfixed) were inverted, sealed with paraffin on to glass slides and transferred to the instrument microscope stage. Cell-associated fluorescence was observed at intervals during incubation at room temperature. Data from single representative 3T3 and SV3T3 fibroblasts are shown in Fig. 3. Both cell types show an increase in RET with incubation. The relative change on 3T3, however, is quantitatively smaller than on SV3T3, and is completed after 15 min of incubation. We conclude that the topographical distribution of C-R complexes on SV3T3 is not random but also that the distribution on 3T3 is not completely random or disperse (although quantitatively the complexes are less clustered than for SV3T3). C-R complexes undergo a limited and rapid approximation on 3T3. By including large segments or even the entire cell in the field the average behaviour of C-R complexes over the whole region is recorded. Because with prolonged culture 3T3 spontaneously lose contact inhibition, we also studied C-R complexes on primary mouse fibroblasts and obtained results identical to those with our strain of 3T3.

Figure 4 shows an experiment in which the monolayers were fixed with paraformaldehyde after incubation at 37°C for

various times. The fixation allowed longer periods for accumulation of fluorescence photons and so there is less scatter of the data points. The same basic features are observed, indicating that fixation did not alter the topography of C-R complexes. At 37°C the aggregation of C-R complexes on 3T3 fibroblasts is completed by the time the first observation can be made at "0" min. But when cells are prefixed and then labelled, the RET obtained shows clearly that the time required for labelling at 4°C and subsequent fixation has allowed significant approximation of C-R complexes. Figure 4 again shows that the relative change of RET on SV3T3 is large but that the change occurs over 1 h even at 37°C .

An alternative method for estimation of RET is based on measurement of the lifetime of the excited state. RET depletes the population of excited donors and thus shortens the lifetime. If a nanosecond flash lamp is used as the exciting source, the lifetime of the excited state can be determined for the label on single cells. The techniques for data collection and analysis have been detailed elsewhere¹⁷. The results obtained from fixed preparations using this method agree qualitatively with the spectral data. Unfortunately, each determination of lifetime requires many minutes of photon counting so that the method was not suitable for observations of living cells nor for surveying large numbers of cells. Additional information on the distribution of bound con A, however, can be obtained from analysis of the fluorescence spectra taken at intervals during the lifetime of the excited donor population (so-called time-resolved spectra). For donors and acceptors separated by statistically variable distances the probability of RET between a donor and the population of acceptors that surround it will also vary. (This is in contrast to the situation in which donor and acceptor are separated by a fixed distance on the same molecule.) Consequently, immediately after excitation the probability of RET will be very high between close donors and acceptors and will decline rapidly as the remaining donors are separated from acceptors by greater distances. In Fig. 5 time resolved spectra from SV3T3 are recorded. The peak at 515 nm corresponds to DANS (donor) emission and decays with time as the excited state is depleted. The second peak at 570 nm results from the

Fig. 4 Ratio of acceptor to donor fluorescence, I_R/I_D , from con A-labelled cells against time. Conditions were as for Fig. 3, except that cells were fixed with 2% paraformaldehyde after incubation but before measurements of fluorescence. Incubation was at 37°C . "Prefixed" specimen was fixed for 20 min at 37°C before labelling. Δ , SV3T3 cells; \bullet , 3T3 cells.

Fig. 5 Time resolved spectra from con A (DANS, rhodamine)-labelled SV3T3 fibroblasts. Photon counts were accumulated at various indicated times after the peak of the light pulse used for excitation. At 2.2 ns RET is high between DANS and nearby RITC. The DANS fluorophores that remain excited at later times are those which are statistically distributed at greater distances from the RITC and thus are less efficient in RET.

rhodamine fluorescence. The relative peak heights of fluorescence, rhodamine/DANS (acceptor/donor) are greatest early during the lifetime of the excited state in accord with the statistical surface distribution of the labelled con A.

The contribution of internalised (pinocytosed) con A to our measurements is probably not significant. We assessed the internalisation by determining the amount of con A that could not be eluted by the competing hapten sugar, α -methylmannoside. For these purposes radioactive (125 I-labelled) con A was used, for at intervals of less than 60 min the amount of internalised fluorescent label gave unreliably low signals. The amount of radioactivity that could not be eluted from dense monolayers in the conditions of our experiments was <10% of the total.

Inherent distribution of con A receptors

In agreement with observations made using other techniques, the approximation of receptors on SV3T3 is significantly greater than on non-transformed 3T3 or primary mouse fibroblasts^{4,5}. In addition, we find that the RET on prefixed SV3T3 is consistently higher than for prefixed 3T3 (example in Figs 3 and 4). This could be because at the high level of resolution afforded by the technique con A receptors are inherently more clustered on SV3T3, that is some of the approximation of C-R complexes on SV3T3 is not induced by the con A. Such an interpretation runs contrary to a large body of evidence using other techniques, indicating the inherent distribution to be disperse on all cell types but it should be emphasised that the degree of resolution afforded by RET exceeds that available by other techniques. Alternatively the surface density of con A receptors on SV3T3 may be higher than for 3T3. Note that this interpretation does not depend on measurements of the actual surface area. This conclusion was originally suggested by Inbar and Sachs¹⁸ and Noonan and Burger¹⁹ but has been difficult to test because of complications in the measurement of cell surface area. Using scanning electron microscopy, Collard and Temmink³ have attempted to account for variations in surface contour and

calculated a significantly greater density of con A receptors on SV3T3.

At the high resolution afforded by RET the topographical distribution of C-R complexes is not random on non-transformed 3T3 or primary mouse fibroblasts. Using the haemocyanin-con A and ferritin labelling techniques, we and others^{4,5} have reported the distribution of C-R complexes to be disperse or random. This conclusion was inferred largely from differences between normal and the more obvious clustered C-R aggregates on transformed mouse fibroblasts. Other groups have not found consistent differences between normal and transformed murine cells²⁰⁻²². Differences have been attributed to variations in cell line and to methodology. Our findings with RET do not completely resolve the issue since the high resolution obtained with RET cannot be compared directly with the topographical descriptions obtained by other techniques. In addition RET provides semiquantitative information integrated over large areas of the surface. Our results, however, suggest that topographical differences between normal and transformed murine fibroblasts are essentially quantitative.

Movement of C-R complexes

In agreement with previous observations involving C-R movement over long distances^{5,23} the non-randomness observed by RET on all cell types is induced to some degree by the con A itself, for prefixed cells or early time points show lesser degrees of RET.

The aggregation of C-R complexes on 3T3 cells is completed in a relatively short time compared with SV3T3 cells. Whether this is because the end point of aggregation represents a lesser degree of organisation or because the organisation is attained more efficiently in the 3T3 cannot be determined from the data reported here.

Quantitative aspects of this slow movement imply that the organisation of C-R complexes observed by RET is not limited by their lateral diffusion over the surface. We re-emphasise that the changes of RET observed require movements of only Ångströms, perhaps 100 Å at the most. A rough calculation of the diffusion coefficient (D) for C-R complexes can be obtained from our data using a well known expression relating the relaxation time of diffusion (τ) to the mean distance (ΔX) travelled by the complexes ($\Delta X^2 = 2\tau D$). For these purposes we can take τ as the time required to attain plateau levels of RET and ΔX to be between 10 and 100 Å. The range of D can then be calculated to be between 10^{-16} and 10^{-17} cm² s⁻¹. This is exceedingly small compared with all previous measurements of movements of antigen-antibody complexes or of succinyl-con A-receptor complexes. For example, experiments²⁴⁻²⁶ utilising the recovery of fluorescence after photobleaching have yielded diffusion coefficients of the order of 10^{-10} cm² s⁻¹ for succinyl con A on fibroblasts (even this is considerably lower than rhodopsin in photoreceptor membranes, 4×10^{-9} cm² s⁻¹). It is interesting that in the experiments of Jacobson *et al.*²⁵ and Schlessinger *et al.*²⁶ recovery from photobleaching was not complete in minutes and suggested a subpopulation of "immobilised" receptors. Even if we assume that the true diffusing species is a con A-cross-linked aggregate involving all bound con A (approximately 10^7 molecules per cell) the diffusion rate, which varies as the square root of the molecular weight, could not be lowered by 6 to 7 orders of magnitude. We suppose instead that the change in RET is not diffusion limited, but represents a secondary organisational change that involves some other mechanism, perhaps the interaction of submembranous structures (microtubules, microfilaments or spectrin-like molecules) with the cross-linked C-R complexes.

Future applications

The extension of RET to the study of the distribution of other surface constituents is obvious. We have reduced the analysis to an empirical semiquantitative one which provides considerable information without forcing assumptions or extensive instrumental corrections that are unreliable and cumbersome. Thus

the method provides a relatively straightforward and reproducible means for obtaining information on distances separating any exogenous ligand that can be labelled with donor and acceptor fluorophores without loss of activity. Distribution can in general be studied in living or fixed material. We have used average signals from large areas of the cell surface. Similar data, however, can be obtained from areas of the surface of as little as 2 μm in diameter, and so regional surface differences can also be compared.

The results obtained with con A serve to direct attention away from the concept of simple unrestricted mobility of surface complexes in the membrane lipid matrix. We predict that RET studies with other ligand-receptor complexes will support the view that cell-surface topography is determined to a large degree by subtle interactions between linked receptors and changes in submembranous elements induced by them.

The crystal structures of a human IgG antibody molecule Kol and a human Fc fragment have been determined at 4-Å and 3.5-Å resolution respectively, by isomorphous replacement. The electron-density maps were interpreted in terms of immunoglobulin domains based on the Rei and McPC 603 models (Kol) and by model-building (Fc). The Fab parts of Kol have a different quaternary structure from that observed in isolated crystalline Fab fragments, there being no longitudinal V-C contact in Kol. The Fc part C terminal to the hinge is disordered in the Kol crystals. It is suggested that the Kol molecule is flexible in solution, whereas fragments are rigid. In the Fc fragment both C_{H3} and C_{H2} show the immunoglobulin fold. The C_{H3} dimer aggregates as C_{H1}-C_L while C_{H2} are widely separated from each other. The carbohydrate bound to Fc is in fixed position. From these structures a hypothetical liganded antibody molecule has been constructed, which is assumed to be rigid.

ANTIBODY molecules serve a dual function: to recognise foreign cells and macromolecules and to trigger the events leading to their elimination. Specific recognition requires surface structures complementary to the antigen and hence a huge variety of antibody molecules. In contrast the effector functions would most economically be performed if all antibody molecules were identical. An antibody molecule of the IgG class consists of two identical light (L) and two identical heavy (H) chains^{1,2}. Each of these polypeptide chains can be subdivided into a constant

region with an amino acid sequence identical to other chains of the same class and a variable region whose sequence varies between antibodies specific for different antigens. Antibody functions are located on different parts of the molecule with recognition lying in a fragment consisting of a light chain and half of the heavy chain—the Fab fragment. Effector function on the other hand resides in the C-terminal half of the heavy chain—the Fc part. There is, however, cooperativity, and effector functions are triggered by antigen binding. How this signal is transferred is open to debate and in this article we will discuss a hypothetical model based on our current knowledge of three-dimensional antibody structure.

Several crystal structures of immunoglobulin fragments (Fab fragments and Bence-Jones proteins) have been analysed during the last few years (for a review, see ref. 3). From the recent crystal structure analyses of a complete human IgG antibody Kol⁴ and a human Fc fragment^{5,6} a coherent view of antibody structure is beginning to emerge.

The crystallographic analysis of the Kol protein was pursued to 5-Å resolution by isomorphous replacement⁴ and later extended to 4-Å resolution. The electron-density map was analysed in terms of domain structure making use of the known structure of the V (variable) and C (constant) parts of the Fab fragment McPC 603³ and the Rei fragment⁷. It was evident that there are differences in domain tertiary structure between the Kol protein and McPC 603. We have not yet tried to analyse these in detail, but it is clear that they do not affect the later discussion on longitudinal domain contacts. A tentative interpretation in the 4-Å map of the C^α chain folding is given for the heavy chain from residue 213 to the -Cys-Pro-Pro-Cys- segment, and for the light chain from residue 209 to the heavy-light chain disulphide (amino acid sequences in the Kol Fab part refer to the McPC 603 molecule³ and to the Rei protein V_L dimer⁸⁻¹⁰). The Fc fragment crystal structure was

*Present address. Institute of Inorganic Chemistry, University of Sydney 2060, Australia.

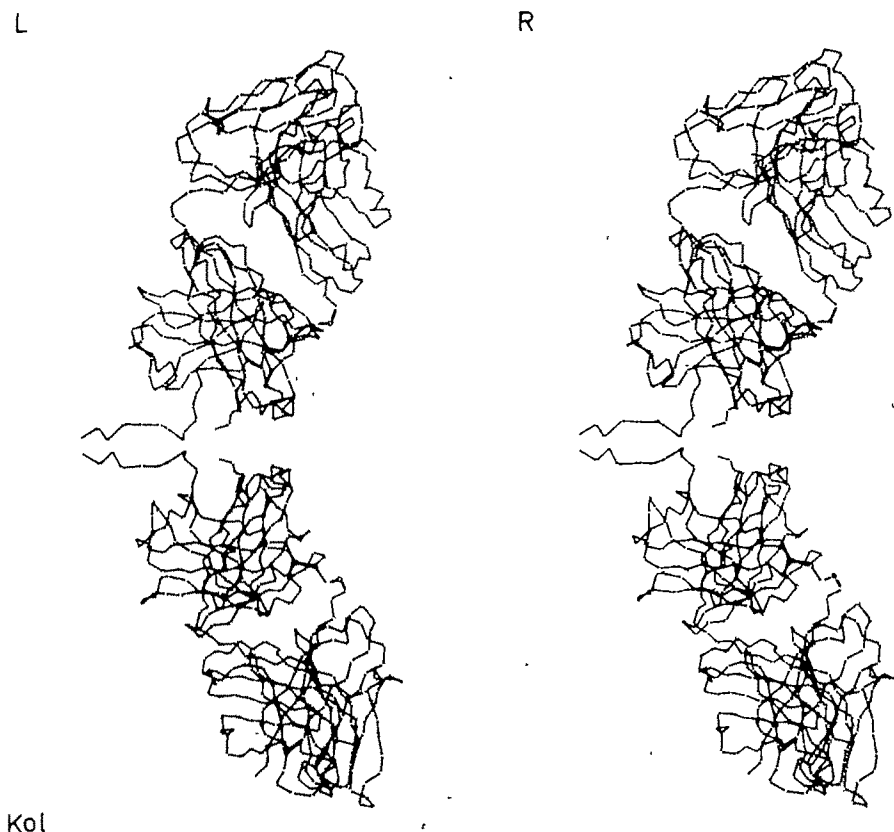

Fig. 1 Stereo drawing of the Kol (Fab)₂ part C*; atom positions were derived by fitting the McPC 603 (ref. 3) V and C dimers to the Kol electron-density map. The coordinates of the C-terminal residues of heavy and light chains and the hinge peptide were obtained by interpretation of the 4-Å Fourier map.

Kol

analysed at 4-Å resolution⁵ and later at 3.5-Å resolution⁶, using isomorphous phases and a complete model was constructed.

The Kol molecule

The C* carbon atom positions of the (Fab)₂ part of the Kol molecule are shown in the stereogram, Fig. 1. The Fab arms subtend an angle of 125°, and the tips of the Fab arms are about 146 Å apart. Except for slight differences in the domain tertiary structure, the V_L-V_H and C_L-C_{H1} dimers appear to be indistinguishable between Kol and McPC 603. In particular, the geometry of aggregation within V and C dimers is very similar. There is a difference, however, in the relative orientation of V and C dimers which can be described by a rotation about an axis through the switch peptides at residues 118-119 (heavy chain) and 109-110 (light chain) (Fig. 2). (Switch peptides are the segments connecting V and C parts comprising residues at 110 (light chain) and 119 (heavy chain).) This, of course, requires a conformational change in the switch peptide segment, which might be accomplished with minimal perturbation as the segment is in an extended conformation. Figure 2 compares the McPC 603 Fab fragment and the Kol Fab part as seen down the switch peptide rotation axis. V_L and V_H, as well as C_L and C_{H1} are related by local diads. These diads subtend an angle (Fab angle) of 135° in the McPC 603 fragment and 170° in the Kol protein, demonstrating the major change in quaternary structure: 'bending the elbow'.

It is already evident from Fig. 2 that in the McPC 603 molecule some residues of V_H and C_{H1} come close to each other. There are 6 C*-C* distances smaller than 6.5 Å (formed by segments 8-10 in V_H and 152 and 207-208 in C_{H1}) and 41 below 10 Å. There are, of course, several contacts between residues of the switch peptide and C_{H1} not included. We believe that these are irrelevant for the later discussion. Equivalent residues of V_L C_L of the light chain adopting the heavy chain conformation are in contact in the Bence-Jones protein dimer structure (ref. 11 and A. Edmundson, personal communication). In contrast, due to the asymmetry of the molecule, V_L and C_L are much further separated in the McPC 603 molecule. There are 2 C* distances below 6.5 Å and 28 below 10 Å.

Through the widening of the Fab angle from 120° to 170° in Kol there is no contact between C* atoms of V_H and C_{H1} smaller than 7 Å. Five distances are below 10 Å. Also, V_L and C_L have no contact (six distances below 10 Å). For comparison, the lateral V_L-V_H and C_L-C_{H1} contacts in the McPC 603 Fab fragment involve nine and seven C* distances respectively closer than 6.5 Å and about 120 distances below 10 Å for both contacts. The C_{H3}-C_{H3} contact in Fc involves 14 C* distances smaller than 6.5 Å and about 150 below 10 Å. According to this admittedly very crude criterion, there is a strong V_H-C_{H1} interaction in crystalline Fab fragment structures while there is no appreciable longitudinal interaction in the Kol Fab parts. In rabbit light chains a disulphide bond links V_L and C_L residues 80 and 172 (ref. 12). A sufficiently close approach in the Kol model occurs between C* atoms of residues 81 and 171 of 9 Å. This distance is 7 Å in the McPC 603 model. The disulphide linkage therefore does not oppose the Fab angle ('elbow') bending considerably. The two Fab arms in the Kol protein have no contact with each other except the covalent linkage of the hinge. There is no approach of C* of the two C_L domains closer than 12.5 Å.

No interpretable electron density is found in the Kol Fourier map which could be assigned to the Fc part⁴. The Fourier map contains significant density in that region where the Fc stem must be located with peak heights about 2.5 times the r.m.s. error in electron density. This is to be compared with the density in the Fab parts with peak heights about four times the error level. We have concluded that the Fc stem is disordered in the Kol crystals, C-terminal to the hinge peptide. Indeed, the (Cys-Pro-Pro-Cys)₂ peptide of the hinge on the molecular and crystallographic diad is only 50 Å away from the crystallographic 3₂ axis. The Fc fragment molecule is too long and too thick to be accommodated on the diad axis^{4,6}. It would interfere with crystallographically related Fc parts. On the other hand, the very close packing in the Kol crystal structure around the hinge peptide (see Fig. 6 in ref. 4) does not allow a close approach of the C_{H2} domains of Fc towards (Fab)₂, but requires a rather extended hinge segment (the hinge peptide is the segment connecting C_{H1} and C_{H2} and containing the inter-heavy chain disulphide linkage).

We constructed a 'minimum disorder' model of the Kol molecule. The Fc fragment structure, when combined with the Fab parts in the Kol crystal structure, should deviate minimally from the Kol crystal symmetry and not violate the crystal packing. The Fc fragment model was placed with its local diad on the crystallographic diad of the Kol lattice so that the hinge peptide, as seen in the Kol molecule and as surmised in the Fc fragment (see later), overlapped. Fc was then rotated azimuthally so that there was minimal overlap with (Fab)₂ parts from crystallographically related molecules. It had to be shifted by about 15 Å along the diad, away from the Fab parts, to avoid overlap. Here it would penetrate the 3₂ axis and interfere with crystallographically related Fc parts. Fc was therefore bent about an axis close to the top of the molecule and perpendicular to the a b plane of the Kol lattice minimally, to avoid this steric interference. It is obvious that these three operations are not independent. Apparently, a correct but intractable three-dimensional treatment would not change the main aspect of the model in a substantial way. Figure 3 represents the model. Evidently there are no contacts between (Fab)₂ and Fc, except the covalent linkage through the hinge peptide, which must have a rather extended conformation. In the 'minimum disorder' model the wide separation of (Fab)₂ and Fc requires this piece of chain to be stretched out. These observations of absent longitudinal interactions between V_H and C_H1 and between C_H1 and C_H2, as well as missing lateral interactions between both C_L parts in the Kol molecule in comparison to the existing V_H-C_H1 interactions in free Fab fragments, will be important in later discussion.

Fc fragment structure

Figure 4 is a stereo plot of the C^α carbon atom positions of the Fc fragment. The molecule has the shape of a Mickey Mouse with the compact C_H3 dimer forming the head, and the C_H2 domains forming the ears. The C_H3 dimer pairing is closely similar to the C_H-C_L pairs found in Fab fragments^{5,6}. C_H2 and C_H3 show the common immunoglobulin fold. They are connected by a loosely folded segment from Ser (337) to Gln (342) which is susceptible to proteolytic attack^{13,14} (amino acid sequence numbers in the Fc fragment are based on the Eu amino acid sequence¹). The longitudinal C_H2-C_H3 contact is characterised by 3 C^α distances less than 6.5 Å (and 43 below 10 Å), not considering contacts made by the connecting peptide. It comprises the segments 247-253 and 310-314 (C_H2) and 376-379 and 428-433 (C_H3) respectively. These segments are homologous to those mediating the V_H-C_H1 contact in Fab fragments described before. The electron density at the C terminus fades away after Ser (442), indicating mobility from this residue on. The N terminus seems to be folded back from Pro (238) on and in intimate contact with the carbohydrate moiety discussed below. This mostly unresolved contact makes an interpretation of the peptide chain conformation around the hinge region difficult at present. A possible chain tracing has

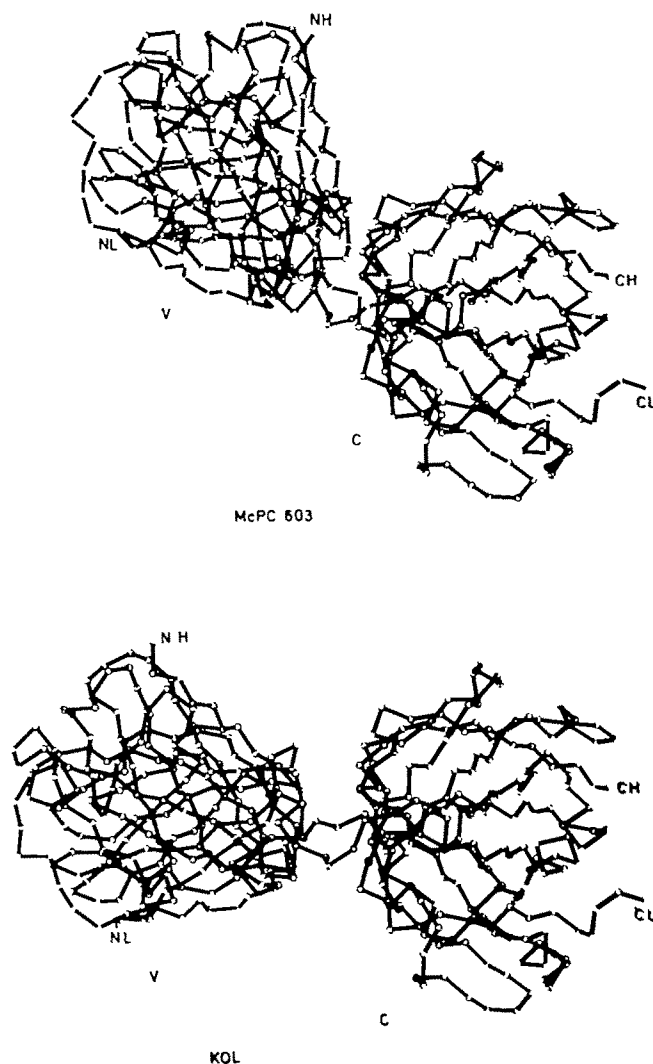

Fig. 2 Comparison of McPC 603 Fab fragment and Kol Fab part. The Fab angle changes by 40°. There is a V_H-C_H1 contact in the fragment, but not in the intact molecule. NH, NL: N terminus of heavy and light chain, respectively. CH, CL: C terminus of heavy and light chain, respectively.

the segment from Gly (236) to Pro (232) in contact with one branch of the carbohydrate chain. The (Cys-Pro-Pro-Cys)₂ segment seems to be disordered. This is not unexpected, as in the Kol crystals the (Cys-Pro-Pro-Cys)₂ segment is fixed while the Fc part is disordered. The electron density assigned

Fig. 3 Stereo drawings of the 'minimum disorder' model of the Kol molecule: they should be regarded as a snapshot of the flexible molecule. There are no contacts between (Fab)₂ and Fc. The structure of the Fc part was derived from the Fc fragment, although we believe that Fc is flexible between C_H2 and C_H3 in the Kol molecule. The hinge peptide is drawn as observed in Kol (Fab)₂ and surmised in the Fc fragment. In order to make the covalent linkage, the hinge which appears to be bent back in between the C_H2 domains has to be stretched out. c.h., carbohydrate.

Fig. 4 Stereo drawing of the C^α carbon positions and the centres of the carbohydrate hexose units of the Fc fragment. The carbohydrate structure was assumed as described in the text. ●, Approximate centres of carbohydrate hexose units. The carbohydrate attachment site is Asn (297). ○, C^α carbon positions. The disulphide linkages are indicated.

to the bound carbohydrate could accommodate a branched carbohydrate chain of the following arrangement.

(H is a hexose unit; at three positions (--) we had difficulties in keeping linked residues in density. The present model is not connected at these positions.)

Such a chain would differ from some carbohydrate sequences of myeloma proteins¹⁸. We have to expect inhomogeneity of the carbohydrate in our material which might make the detailed analysis difficult. The crystallographic analysis of the carbohydrate structure requires further structure refinement. The carbohydrate moiety covers a large part of the C face of the C_{H2} domain.

Our model indicates that the carbohydrate covers apolar residues on the C face, among these being: Phe (241), Phe (243), Val (262), Val (264), Val (266). The site of attachment of the carbohydrate moiety at Asn (297) is part of a reverse turn. The four residues in the turn are Tyr-Asn-Ser-Thr. In general, carbohydrate attachment preferentially occurs at amino acid sequences X-Asn-X-Thr(Ser) (see review, ref. 16). Pancreatic trypsin inhibitor (PTI) and ribonuclease are molecules of known three-dimensional structures¹⁷⁻¹⁹. There exist closely related variants of these molecules (colostrum inhibitor²⁰ and ribonuclease B²¹) which carry carbohydrate. The carbohydrate site is part of a bend in all cases. The detailed conformations are very different, however.

Domain tertiary structure comparison

A set of comparative drawings of the individual domains in the Fab fragments McPC 603 and New, and the Bence-Jones proteins Mcg and Rei has been published³. A detailed comparison with the chain folding in the (Fab)₂ part of the Kol molecule has to await higher resolution data of the Kol crystals.

Comparative drawings of the chain folding of V, C_{H1} , C_{H2} and C_{H3} domains have been prepared and are shown in ref. 6. The most prominent differences between V and C domains lie in loops mediating V-V and C-C aggregation respectively. According to these criteria, it is clear that Fc C_{H3} has the characteristics of a C domain: the long loop involved in the C-C interface is present with the segment 398-403 forming the corner. V-characteristic loops are absent. C_{H2} , however, has some of the features of a V domain: the V characteristic loop is present, but shorter than in V domains. The C characteristic loop is also present, but shorter than in C domains and longer than in V domains. This raises the interesting question of the evolutionary origin of the C_{H2} segment. While amino acid

sequence homologies have been interpreted as indicating a close relation of C_{H2} to other C segments and only a distant relation to V segments, the structural comparison points to an intermediate structure. There is a remote possibility that the type of aggregation influences chain folding, the C_{H2} conformation being characteristic of a free domain, and the other C segments being deformed by their C-C contacts.

Domain-domain interactions

(1) Lateral interactions. The lateral V-V (V_H - V_L , V_L - V_L) and C-C (C_L - C_{H1} , C_L - C_L) interactions observed in Fab fragments^{22,23} and Bence-Jones proteins^{10,24} have been described in great detail and, will not be considered here. The relative arrangement of the two C_{H3} domains observed in the Fc fragment is closely similar to the C_L - C_{H1} aggregation observed in McPC 603. The C_{H2} domains have no contact with each other except the covalent linkage through the hinge. It is an intriguing question why C_{H2} forms neither the familiar C-C nor V-V contact. It has been suggested that the tertiary structure of the C_{H2} domain does not resemble a C but also lacks some features of a V domain. This might prevent dimerisation. In the presence of the spatially fixed carbohydrate moiety formation of the C-C contact is impossible. Furthermore, some of the hydrophobic residues in C_{H3} , which lie close to the local diad, and are probably important for the contact, are replaced by polar groups in C_{H2} . An analogous argument holds against a potential V-V contact.

(2) Longitudinal interactions. In the Kol protein and the 'minimum disorder' model derived from it, no longitudinal contacts are observed between V_H and C_{H1} , V_L and C_L , and C_{H1} and C_{H2} . There are also no contacts between the Fab arms. In view of this lack of stabilisation along the chain, it is difficult to assume that the Kol molecule should be rigid in solution. We rather presume that flexibility exists between V and C dimers ('elbow' V-C flexibility), between the Fab arms ((Fab)₂ flexibility) and between Fc and (Fab)₂ (Fc-(Fab)₂ flexibility). As mentioned before, flexibility between Fc and (Fab)₂ could explain the weak, uninterpretable electron density for Fc in the Kol crystals. The relative positions of V and C dimers and Fab arms are frozen in the Kol crystal lattice dictated by crystal packing requirements. Even the C_{H2} segments might sit flexibly on the C_{H3} dimers (C_{H2} - C_{H3} flexibility) in the Fc part in the Kol protein in contrast to their fixed position in the fragment. We have, of course, no evidence for this as the Fc part in the Kol crystals is not yet analysed. Rigidity without longitudinal contact between the domains could only be brought about if the switch peptides and the hinge peptide adopted rigid conformations. These segments are in an extended conformation, largely exposed to solvent. Inherent rigidity of these peptide chains is improbable.

The model which we would like to propose for the Kol protein and for other unliganded IgG molecules is a highly flexible one.

The degree of segmental flexibility appears more limited for V-C ('rotation' about 'switch axis') than for (Fab)₂ or Fc-(Fab)₂, which are connected by far longer extended polypeptide chains.

In obvious contrast, the Fab fragments and the closely similar Bence-Jones protein dimer appear to be rigid molecules. In the three structures, V and C dimers subtend a similar Fab ('elbow') angle of 120° to 135°. Crystal packing is different in the three crystal structures and would be unlikely to have the same effect on the Fab angle if it were variable. Indeed, a longitudinal contact exists between V_H and C_{H1} in these fragments as described before. This contact surface is smaller in size than the lateral C-C or V-V contacts, but it has been found in other systems that small contact surfaces may mediate strong binding (PTI-inhibitor-trypsin²⁵). In the Fc fragment C_{H2} and C_{H3} form a contact as described. The linking peptide is not in a completely extended conformation but is irregularly bent between residues Lys (338) and Gly (341). The presence of two nearly identical contacts in crystallographically non-identical environment speaks for a rigid Fc fragment, although it would be desirable to confirm this by structure analyses of different crystal forms.

It is remarkable and deserves further consideration that homologous segments mediate the close V-C contacts in the Fab fragment and the close C_{H2}-C_{H3} contacts in the Fc fragment: V_H, residues 8-10; C_{H1}, residues 152 and 207-208 (McPC 603); C_{H2}, residues 247-253 and 310-314; C_{H3}, residues 376-379 and 428-433.

These contacts have been inferred from C^{*} distance calculations. The actual bonding interactions are, of course, made by side chains and/or polar atoms of the backbone. These segments contain residues highly conserved in immunoglobulin subclasses and classes. Of particular interest is the conservation of the three hydrophobic residues in C_{H2} (Leu-Met-Ile (251-253)) in all IgG subclasses, but also in IgM C_{H3} (Ile-Phe-Leu (352-354))²⁶ IgA C_{H2} (Leu-Leu-Leu (256-258))²⁷ and IgE C_{H3} (Leu-Phe-Ile (339-341))²⁸. We note in passing that this observation adds to the evidence that in IgM and IgE, which contain an additional constant domain, C_{H3} resembles C_{H2} in IgG. In C_{H1} and C_{H3} ('top' contact area) the contact residues are from the bends C-terminal to the two intra-domain Cys residues. In V_H and C_{H2} ('bottom' contact area) these are predominantly residues of the bend N-terminal to the first intra-domain Cys residue. It is of further interest that the top contact segments described for C_{H1} and C_{H3}, when projected into a V segment, coincide with the first and third hypervariable segments forming the antigen-binding surface in V dimers.

In an allosteric immunoglobulin model which we will propose in a later discussion, the signal transfer through the domains from the top contact to the bottom contact occurs along homologous segments in all domains.

The rigidity of Fab and Fc fragments and the segmental flexibility in the complete molecule Kol might just be a coincidence and future studies might provide a better statistical sample

of the whole population of molecules. The following model-building studies and discussion are based on the hypothesis that (1) rigidity and segmental flexibility are indeed inherent properties of fragments and complete, unliganded molecules, respectively, and (2) the rigid Fab fragment structures are characteristic for the liganded molecules. This is primarily based on the observation that Fab fragments show no gross structural change upon hapten binding^{22,23}. We are aware that different explanations for this observation are possible. In particular, hapten binding might be insufficient to produce structural changes brought about by antigen.

We constructed a hypothetical liganded antibody molecule by combining the fragment molecules. Starting with the Kol (Fab)₂, we set the Fab elbow angle to 120°, which is characteristic for Fab fragments. The hinge peptide, which is well defined in the Kol crystals and less well ordered—but apparently bent back—in Fc fragment crystals were superimposed with the local diads coinciding. Fc was then rotated azimuthally in order to avoid overlap between C_{H1} and C_{H2} of the same molecule. A narrow range of the azimuthal angle turned out to be possible. The resulting model is shown in Fig. 5. C_{H1} and C_{H2} are close at the bottom and top contact segments discussed before, which comprise conserved residues in immunoglobulin subclasses and classes. The hinge peptide forms numerous internal contacts with both domains and the carbohydrate. It is obvious that in view of the (Fab)₂ flexibility of the Kol molecule, the choice of the relative arrangement of the Fab arms was arbitrary. By a (Fab)₂ rearrangement the formation of a lateral contact between the Fab arms appears possible.

The important aspect of this model, which we want to emphasise, is that all longitudinal interdomain contacts are closed, resulting in a rigid structure. (Fab)₂ bending is prohibited by the C_{H1}-C_{H2} interaction.

We suggest that antigen binding causes a stiffening of the flexible antibody molecule by formation of the longitudinal inter-domain contacts described. The largest structural change involves the folding of the hinge peptide in between the C_{H2} globules to allow the C_{H1}-C_{H2} approach. This model allows deletion of a large proportion of the hinge segment as observed in two crystalline antibodies^{29,30}, without change in the relative Fab Fc arrangement, in contrast to the flexible model with the extended hinge segment as described before. The hinge deletion forces C_{H1} and C_{H2} to form the contact. This could induce an overall quaternary structural change to the rigid conformation. The Fab bending produces a model more like a T compared to the Y of the Kol molecule (Figs 3 and 5). A T-shaped model has been suggested from low resolution X-ray studies of the myeloma protein Dob³¹. This protein has a hinge deletion³². Electron micrographs of hapten cross-linked antibodies generally show a short Fc stem as we would expect from Fig. 5^{32,33}.

Segmental flexibility between Fab and Fc parts of antibody molecules is experimentally established by spectroscopic and hydrodynamic observations^{34,35}. Hydrogen-exchange experiments, as well as experiments with limited proteolysis of IgM and their Fab fragments, may be interpreted in terms of a less flexible fragment structure^{36,37}.

There are several observations of structural changes in

Fig. 5 Stereogram of a hypothetical liganded IgG molecule. The molecule is T-shaped with Fc forming the stem. Fc and (Fab)₂ are in close contact. The hinge peptide is folded back in between the C_{H2} parts. c h., carbohydrate.

antibody molecules upon antigen binding. Circular polarisation of fluorescence (CPL) changes in complete antibodies upon antigen binding, but not in Fab fragments^{38,39}. An antigen-induced volume contraction has been found by small angle X-ray scattering in complete antibodies, but not in Fab fragments^{40,41}. Antibodies seem to lose flexibility on antigen binding^{42,43} and to gain conformational stability against denaturation⁴⁴. The structural difference in the Fab part between complete antibody and Fab fragment ('elbow' bending) might manifest itself in a change of the characteristics of ligand binding. Observations of differences in rate constants of fragments and complete antibodies are controversial^{45,46}. There are, apparently, no significant hapten binding affinity differences between Fab fragments and complete antibodies, indicating that there is no cooperativity between the two hapten binding sites in an antibody molecule⁴⁷. This does not contradict the ligand-induced structural change proposed, as the energy required for the conformational change might be provided by an increased ligand affinity with both effects cancelling out. There are indeed observations on IgM molecules of differences in thermodynamic parameters for haptens and antigens⁴⁸, interpreted as indicating an antigen-induced structural change.

Before the X-ray structure determination of a liganded antibody molecule, there are experiments that could disprove or verify the hypothetical model of ligand induced conformational changes proposed. Chemical modification of residues participating in the longitudinal inter-domain contacts might help in determining the origin of the spectroscopic signal produced by ligand binding^{38,39}. The hinge peptide undergoes the most extensive local structural change in our model. This should be reflected in the kinetics of disulphide reduction or proteolytic cleavage. The crystal structure analysis of the Fab fragment Kol is under way in our laboratory. This molecule we would expect to be in the bent conformation. Detailed X-ray models of the IgG molecules Dob^{39,41} and Mcg^{39,49}, which have a deletion in the hinge region, would be of great interest, as they might resemble liganded molecules.

We have used the PROTEIN program system written by Dr Wolfgang Steigemann in this laboratory. We thank Drs G. Schwick and H. Haupt, Behringwerke, Marburg, for providing the Fc material, Frau K. Epp for X-ray technical assistance and the Deutsche Forschungsgemeinschaft and Sonderforschungsbereich 51 for financial assistance.

Received April 5, accepted October 11, 1976.

Atmospheric gravity wave production for the solar eclipse of October 23, 1976

CHIMONAS and Hines¹ suggested that during a solar eclipse the cool shadow of the Moon moving with supersonic speed through the Earth's atmosphere should generate bow waves. Upper atmospheric disturbances, having quasi-periods of some 20 min, were recorded^{2,3} after the eclipse of March 7, 1970, and were regarded as possible verification of Chimonas and Hines's¹ suggestion. Other observations^{4,5} following the eclipse of June 30, 1973, failed to detect such disturbances. The eclipse of October 23, 1976, will provide another opportunity in attempting to record eclipse-generated atmospheric disturbances.

As a result of the curvature of the eclipse path and variations in speed of the Moon's shadow, focusing of the waves should occur at calculable positions and times^{6,7}. Enhanced amplitude in a focal region should provide optimal conditions for verifying the existence of the bow wave⁷. We have made calculations of the form of the bow waves expected for the eclipse of October 23, 1976, and in particular the positions and times at which focusing effects are expected, using the eclipse path calculated by Fiala and Duncombe⁸, and the technique outlined by Beer and May⁹. Figure 1 shows the calculated positions of the northwards and southwards moving bow wave-fronts, as plots of constant time, T . Ray paths lying along great circles, are also indicated for disturbances originating at time t .

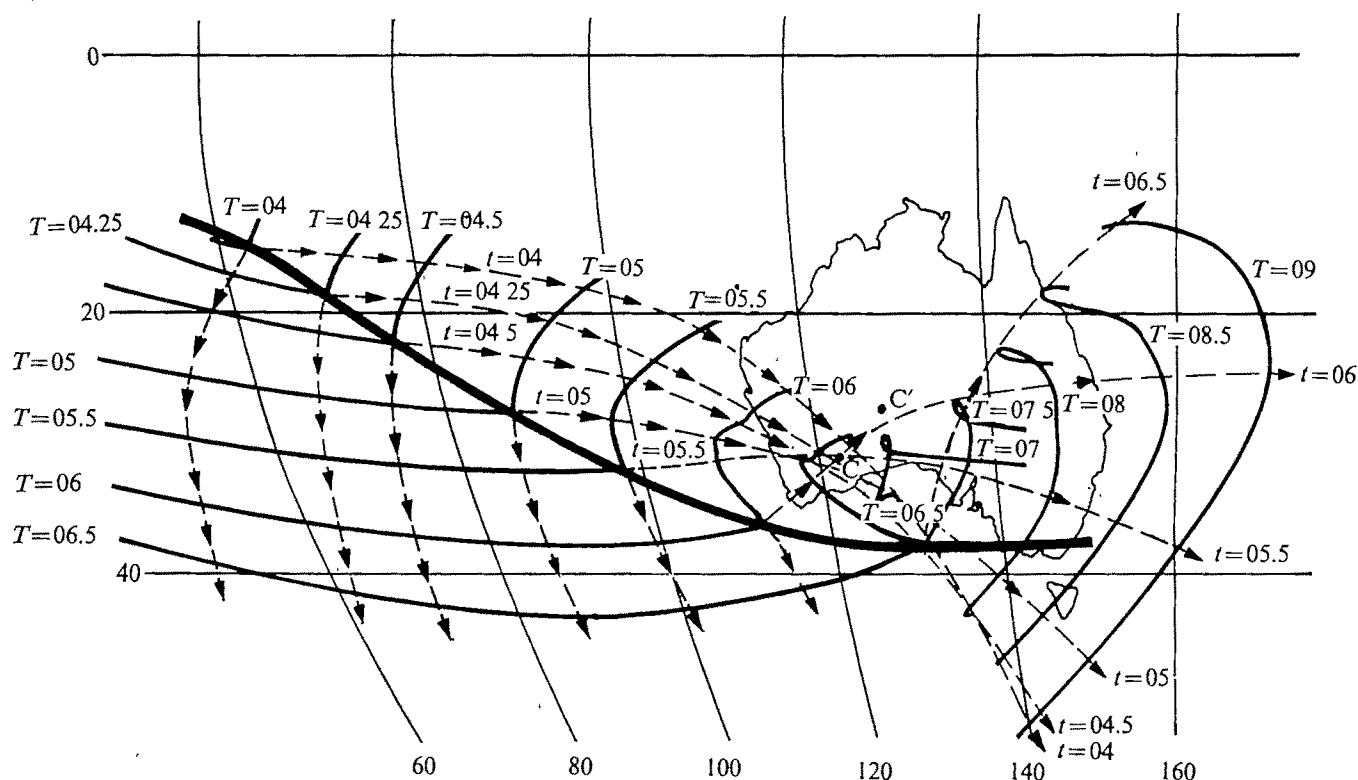

Fig. 1 Focusing of bow waves. The eclipse path is represented by a heavy continuous line. The wave fronts (continuous) are drawn for constant values of T . Ray paths (dashed) are shown for disturbances originating at times t . C_L is taken to be $10.3^\circ \text{ h}^{-1}$. When a value of 7.8° h^{-1} is assumed, the focus at C moves to C' .

The calculations were made for two values of C_L , the velocity of propagation of the bow wave, namely $10.3^\circ \text{ h}^{-1}$ (320 m s^{-1}) and 7.8° h^{-1} (290 m s^{-1}). Actual propagation velocities of long period internal gravity waves are likely to be between these values.

A well defined focus, near C in Fig. 1, appears in Western Australia where the southwards waves generated between approximately 0400 UT and 0600 UT tend to converge for $C_L = 10.3^\circ \text{ h}^{-1}$. C' in Fig. 1 indicates that focus for $C_L = 7.8^\circ \text{ h}^{-1}$.

Table 1 Approximate position and occurrence time of focus

C_L ($^\circ \text{ h}^{-1}$)	7.8	10.3
Latitude ($^\circ \text{S}$)	27	32
Longitude ($^\circ \text{E}$)	127	123
T (UT)	07.5	06.6

h^{-1} . The approximate position and T for the foci are indicated in Table 1. C and C' identify a comparatively small region where enhanced bow wave amplitude should occur.

The focus is well within the penumbra region where the bow wave contains predominantly shorter wavelength components. Quasi-periods of ~ 20 min should therefore be observed^{2,3}, rather than longer periods of some 4 h which should predominate at great distances¹⁰.

Some aspects of the discussion are over-simplified. Firstly, the eclipse path is regarded as a curved line following the path of totality, so that disturbances generated within the penumbra are ignored. Secondly, the discussion considers only geometrical optics, whereas diffraction effects will produce a more diffuse focus than indicated in Fig. 1. A disturbance period of ~ 20 min corresponds to a wavelength of 350–400 km, which will be the order of the diffraction pattern diameter.

Finally, the bow wave is assumed to propagate at constant speed along great circles, and complications arising from the structure of the atmosphere are ignored.

The recording of ground level microbarograph and ionospheric disturbances in the focal region would be most interesting.

Argon fluorescent X rays in the Earth's atmosphere during solar flares

THE satellite Ariel V carries a proportional counter pointed along the spin axis. We report here the detection of a strong flux of X rays coming from the sunlit Earth during two large solar flares. These albedo X rays are proportional to the solar X-ray flux and consist of scattered X rays and a strong fluorescent line at 3 keV from atmospheric argon. There is also a weaker line at ~ 7 keV which is probably present in the incident solar spectrum.

The MSSL proportional counter (Experiment C) on Ariel V is a 92-cm² aperture, 85- μm thick Be window, Xe-filled counter. The field of view is circular with FWHM = 3.5° and is inclined 1.75° to the spin axis. This results in a field of view

(FOV) of 5.2° FWHM for the observations to be described. The experiment operates in one of two gain modes originally covering the energy range 1.5–20 keV.

Ariel V is in a near equatorial orbit with inclination 2.9° , apogee and perigee 543 and 501 km, and period 102 min. The satellite spins about its axis once every ~ 6 s.

During the flare of March 28, 1976, the experiment was in a low-gain multiscaler mode. The data recorded were total counts in the energy range 2.0–6.3 keV as a function of time in 64-s intervals.

During the flare of April 30, 1976, the experiment was in a spectral mode. The pulse height spectrum was recorded in 32 channels covering the energy range 1.5–9.5 keV and integrated over each orbit. Since the experiment operates only when the satellite is in sunlight, and is turned off when in the region of high charged particle flux over the South Atlantic, the average on-time is ~ 50 min. During this time the satellite views in sequence: a region of space containing the cosmic X-ray source of interest, the sunlit Earth, and the dark Earth. The sunlit Earth was a very strong X-ray source during the flare on April 30. The spectrum of the sunlit Earth was easily derived using the spectra recorded during the previous orbits (before the flare) as background.

For the flare on March 28, the spin axis was pointed at RA = 235° , dec. = $-1^\circ 6'$. No strong X-ray sources were in the FOV. The counting rate pointed at space was ~ 2 counts s^{-1} . This decreased to ~ 1 count s^{-1} when the dark Earth passed through the FOV and diffuse X rays from space were cut off. Just after the flare the rate increased to 5,000 counts s^{-1} when the sunlit Earth was viewed. Since the space rate remained at ~ 2 counts s^{-1} , there is no doubt that the sunlit Earth was the source of this signal.

The solar X-ray flux was monitored in two energy bands by NOAA ion chambers aboard the satellite GEOS 1 (ref. 1). These bands were 1–8 Å (1.5–12 keV) and 0.5–4 Å (3–24 keV). Ariel data can be normalised to the solar 1–8 Å flux or the 0.5–4 Å flux. The scattered flux seems to decay at about the same rate as the solar flux in either of these bands. We will use the 1–8 Å band because the ion chamber which produces these data has a window of about the same thickness as that of the Ariel detector. During the two flares which we observed, the solar flux in the 0.5–4 Å band was one tenth of that in the 1–8 Å band.

Figure 1 shows that the solar flux can be used to predict the X-ray strength of the sunlit Earth. When the solar flux is

Fig. 1 The solar X-ray flux in two energy ranges, (—, 0.5–4 Å; ---, 1–8 Å) recorded during the flare of March 28. The right hand scale refers to the solar flux. The scale factor for each curve has been indicated. Note that the two curves have been normalised. The short heavy lines are the normalised counting rate of the Ariel detector. These rates are given on the left hand scale and the numbers (for example, 8,051) are orbit numbers. As expected, the albedo X rays follow the measured solar flux.

Fig. 2 The solid curve is the predicted dependence of scattered X-ray flux on scattering angle. It has been normalised to data taken during orbit 8,055 (x) to show that we understand the basic scattering geometry.

$5 \times 10^{-7} \text{ W m}^{-2}$ in the 1–8 Å band the scattered signal is expected to be about the same as the space background. Normally, when the Sun is not active, solar energy is $< 10^{-7} \text{ W m}^{-2}$ and the sunlit Earth is not a large source of background in our energy range. (This is not at all the case for softer X rays, particularly < 1 keV where fluorescent N and O lines are strong².)

Before deriving the scattered solar flux it is necessary to consider the geometry of our observation. Figure 1 shows that during each orbit the Ariel counting rate decreased much more rapidly with time than the solar X-ray flux. Since the satellite spin axis remains fixed in space, as the satellite circles the Earth it views different areas of the top of the atmosphere, and the angle that detected scattered X rays make with the terrestrial radius vector changes. The total thickness of atmosphere that these X rays must traverse, to travel from Sun to Earth to detector, also changes. Thus the detected scattered flux depends strongly on the position of the satellite in its orbit.

A simple calculation fits our data well. For these particular observations, the top of the atmosphere viewed by the detector was approximately planar, the X-ray absorption coefficient was almost the same for incident and scattered X-ray, there was only single scattering, and the cross-section did not vary much with angle (the scattering angle was always $> 90^\circ$). If the angle between the path of the incident X ray and the radius vector is ϕ , the angle between the path of the scattered X ray and the radius vector is θ , and the solar flux is f_0 , then the scattered flux at the satellite, f_s , is

$$f_s = \text{constant} \times f_0 \left\{ 1 + \frac{\cos \theta}{\cos \phi} \right\}^{-1}$$

This is shown in Fig. 2.

The agreement with our data is quite good considering that we have not smeared the prediction over the 5° detector FOV and that we have not included the time dependence of the solar flux.

The maximum flux in Fig. 2 corresponds to a time when the satellite views the sunlit limb of the Earth and the detector is looking parallel to the top at the atmosphere ($\theta = 90^\circ$). When the scattered flux drops rapidly to zero the detector is looking at the terminator ($\phi = 90^\circ$) and solar X rays are absorbed before they reach that part of the atmosphere viewed by the detector.

We note that scattering in our energy band must occur predominantly at altitudes between 70 and 90 km. At these altitudes and at sea level $\sim 1\%$ by volume of the atmosphere is argon.

We also note that Harries and Francey³ observed scattered solar X rays in the range 2–6 keV and showed that their rocket-borne detector background was consistent with this.

For the flare of April 30, spectra were recorded during orbits 8,555 and 8,556, which both showed a scattered solar continuum and a strong argon fluorescent line. We have analysed the data from orbit 8,555 which were recorded on April 30 from 2144 to 2203 UT. During this interval the solar flux averaged $2 \times 10^{-5} \text{ W m}^{-2}$ in the 1–8 Å band⁴.

Fig. 3 X-ray energy scattered from the sunlit Earth measured during orbit 8,555. The argon fluorescent line and a scattered solar Fe XXV line(s) can be seen superimposed on the solid line which approximates the scattered solar continuum. Error bars show counting statistics only. Above 8 keV there is an additional uncertainty caused by background subtraction. The deviation of the last points from the line is not significant.

A continuum shown as a solid line in Fig. 3 was subtracted from the data to yield the line profile shown in Fig. 4. The energy and width of the line at ~3 keV are very close to the expected response of our detector to the argon line. The line is not exactly centred at the expected energy of 2.95 keV, because of the uncertainty in our detector calibration. The relative strength of the line and scattered continuum are as expected. This feature is without doubt the argon fluorescent line.

The solar spectrum during a flare consists of a continuum with strong lines due to Si XIII at 1.8 keV, Si XIV at 2.0 keV,

Fig. 4 The observed line shape compared to the expected detector response to a line at ~3 keV. Error bars are counting statistics only and do not include uncertainties in the continuum which has been subtracted.

Ca XIX at 3.9 keV and Fe XXV at 6.5 keV (ref. 5). The scattered Fe XXV feature is present in the spectrum illustrated in Fig. 3, but the other lines, if present, are hidden by the fluorescent A line at 3 keV.

We assume that the detector was looking at the Earth in the same direction as incident solar radiation ($\theta = \phi$), and also that the satellite was in a near-Earth orbit, so that the Earth can be considered as a planar source and the detector count rate is independent of altitude. The numbers following are calculated for a solar flux of $1.0 \times 10^{-4} \text{ W m}^{-2}$ in the 1–8 Å band, the maximum flux during each of the two flares we observed.

From the spectral data we derive 550 argon photons $\text{cm}^{-2} \text{ s}^{-1} \text{ ster}^{-1}$. This is approximately equal to the number of scattered photons $> 3.2 \text{ keV}$.

The total albedo energy from 1.5 to 9.0 keV (1.4–8 Å) is $1.5 \times 10^4 \text{ keV cm}^{-2} \text{ s}^{-1} \text{ ster}^{-1}$. This is equivalent to 1.5×10^{-3} of the incident solar energy re-emitted into 2π steradians. Eleven per cent of this albedo energy is in the argon line. The strength of the argon fluorescent line has been calculated by Aikin⁶ for quiet Sun conditions, but our observations do not agree—we get a factor of 100 less than Aikin.

For our detector, the rate at the peak of the flare caused by the X-ray albedo (1.5–9 keV) was 440 counts s^{-1} , 100 counts s^{-1} came from the A line and 7 counts s^{-1} from the scattered Fe line.

The X-ray flux from the Sun is normally $< 10^{-7} \text{ W m}^{-2}$ in the 1–8 Å band. Thus the normal background contribution of the sunlit Earth should be $< 0.4 \text{ counts s}^{-1}$. By way of comparison the dark-Earth background is 1 count s^{-1} and the background looking at a source-free region of space is 2 counts s^{-1} .

We thank the SRC and the USERDA for support, and Prof. R. L. F. Boyd, and the MSSL for hospitality. B. H. was on study leave from the University of Adelaide, Australia.

Penetration of interstellar dust into the Solar System

THE Sun moves through local interstellar matter with a velocity of $\sim 20 \text{ km s}^{-1}$ (refs 1–4). Bertaux and Blamont⁴ have suggested that interstellar dust grains streaming into the Solar System are focused by the gravitational attraction of the Sun and that, as a consequence, the density of these dust grains is strongly peaked on a line extending from the Sun backwards in the downstream direction. Comparison of the predictions of this focusing model with direct observations of the dust⁵ (which do not show this large peak) leads Bertaux and Blamont to suggest that interstellar dust particles are underabundant in the Solar System by a factor of ~ 100 , compared with the usual picture of the density of interstellar grains. They suggest a number of possible explanations: first, the experiments are only sensitive to a fraction of the dust particles; second, radiation pressure or some other process eliminates the particles; third, the interstellar gas and dust near the Sun are abnormal. We point out here that a general effect not considered by Bertaux and Blamont offers a natural explanation of the observations. Grains, both in interplanetary and in interstellar space, will, in

general, carry a net electric charge, and the Lorentz force is strong enough to destroy gravitational focusing.

Several processes contribute to the charging of grains in space. The ejection of photoelectrons and the accretion of ions tends to charge the grains positively, while the accretion of electrons produces a negative charge. Since the cross section for the accretion of charged particles depends on the electrical potential of the grain⁶ the equilibrium charge state is given by a relation of the form

$$\sigma_e(V_0)f_e = \sigma_i(V_0)f_i + \gamma\sigma_{ph}f_{ph} \quad (1)$$

where the σ are the cross sections of the grains for electrons, ions and energetic photons and the f are the fluxes of electrons, ions and energetic photons; γ is the photoelectron yield (typically ~ 0.1 (ref. 7)) and V_0 is the electrical potential of the grain. Watson⁷ has computed the equilibrium electrical potential of grains in the interstellar medium to be positive, from ~ 0.1 V in cool, dense regions of interstellar space to ~ 3 V in hot tenuous regions. Grains impinging on the Solar System are thought to originate in a hot tenuous region⁴ and would thus be charged to ~ 3 V. Within the Solar System grains are subjected to large fluxes of electrons and ions from the solar wind and to energetic photons from the Sun. The photon flux is larger than the electron flux, so the grains are positively charged to a potential estimated at ~ 10 V (ref. 8). The sign of the potential is irrelevant to our argument.

A grain of radius a charged to a potential V_0 carries a net charge

$$q = aV_0/300 \text{ e.s.u.}$$

If the grains have radii⁴ of 2×10^{-6} cm and a nominal electrical potential of 5 V, then $q = z|e| \simeq 3.3 \times 10^{-8}$ e.s.u. (corresponding to a deficit of ~ 70 electrons per grain).

The Lorentz force exerted by the solar wind magnetic field on a grain having velocity V_g is

$$\mathbf{F}_L = q \left[-\frac{\mathbf{V}_{sw} \times \mathbf{B}_\perp}{c} + \frac{\mathbf{V}_g \times \mathbf{B}}{c} \right] \quad (2)$$

where \mathbf{B}_\perp is the component of the magnetic field perpendicular to the radial solar-wind velocity vector. The solar-wind velocity, V_{sw} , is ~ 400 km s⁻¹, so the initial velocity of the grain makes a negligible contribution to the Lorentz force. If we denote by \mathbf{B}_\perp^0 the transverse component of the magnetic field at the orbit of Earth and assume the field to have an Archimedian spiral structure⁹, then equation (2) can be written

$$|\mathbf{F}_L| = \frac{qV_{sw}|\mathbf{B}_\perp^0|}{c} \frac{\sin\theta}{r} \quad (3)$$

where r is expressed in astronomical units and θ is the solar colatitude angle. Then if \mathbf{F}_G denotes the gravitational attraction of the grain by the Sun

$$\frac{|\mathbf{F}_L|}{|\mathbf{F}_G|} = \frac{(2.25 \times 10^{26})qV_{sw}B_\perp^0 r \sin\theta}{GM_\odot mc} \quad (4)$$

where as above $z = |q/e| \sim 70$. Estimating the radius of the solar wind cavity to be ~ 50 AU, and taking the average value of $\sin\theta$ to be ~ 0.5 , for the grains treated in the gravitational focusing model, $F_L/F_G \sim 10$ at the orbit of Earth, and $F_L/F_G \sim 500$ in the outer reaches of the solar wind. Thus it is clear that unless the estimates of the grain charge are grossly in error, the Lorentz force dominates the motion of all but the most massive grains throughout most of the Solar System; the Sun's gravitation is a minor perturbation to the motion of small, electrically charged grains in the Solar System.

The precise effect of the Lorentz force on the trajectories of grains depends on the geometry of the interplanetary magnetic field. There is evidence that the interplanetary field has a generally uniform large scale structure¹⁰. For our purposes, it is sufficient to compare the deflection of a grain produced by the Lorentz force to that produced by the Sun's gravity. A grain moving at an average velocity of 30 km s⁻¹ spends ~ 8 yr crossing to the centre of a 50-AU solar wind cavity. In that time the Sun's gravity deflects the grain's trajectory less than a radian, corresponding to a transverse velocity increment of ~ 10 km s⁻¹. Integrating the Lorentz force (equation 2) over a particle's trajectory yields a transverse velocity increment $|\Delta V|$ about equal to the smaller of $8.6 \times 10^6 z \ln(r_0)$ cm s⁻¹ or V_{sw} , where r_0 is the radius of the solar wind cavity in astronomical units. For $z \simeq 70$ and $r_0 \simeq 50$, $\Delta V \sim 400$ km s⁻¹. This corresponds to the particle being 'picked up' by the solar wind, gyrating about the magnetic field, and being convected out of the Solar System. The precise structure of the magnetic field or the details of the grain's motion are not relevant to our main point, which is that deflection of charged grains by the Lorentz force will obliterate the gravitational focusing effect so that one should not expect to see the predicted peak.

The reader can easily convince himself that the conclusion is not strongly dependent on the parameters used in this discussion. Interstellar grains (except those having a charge to mass ratio $\leq \sim 10^{-3}$ of that presumed here) will not undergo solar-gravitational focusing and will, in fact, be largely excluded from the Solar System by the sweeping action of the solar wind magnetic field.

We are grateful to N. J. Woolf for a helpful discussion. This work was supported in part by NASA.

Seiches in supergranules

THE recent report by Hill, Stebbins and Brown¹ of oscillations of an apparent solar radius has stirred a mild controversy². In particular, the failure of Grec and Fossat³ to detect Doppler variations with similar periods in solar spectral lines provides striking contrast with the results of Hill *et al.* Both sets of observations have been carefully performed and thoughtfully analysed and, if one accepts both sets of results at face value, the problem of reconciling the two must be confronted. Here we consider seiches in supergranules as a possible cause of the discrepancy.

Hill *et al.* in Arizona detected a discrete spectrum of oscillations in an effective diameter of the Sun, with periods decreasing from ~ 1 h. Apparent variations in this diameter can be caused by changes in the limb darkening function arising from temperature and density perturbations, but, if one assumes that the measures correspond to variations of the radius, one infers motions of the solar surface with velocities ~ 10 m s⁻¹. On the other hand Grec and Fossat in Nice have measured

the radial velocity of the solar material, averaged over the bulk of the solar surface, and find no motion with mean velocities $> 70 \text{ cm s}^{-1}$ on timescales $\sim 1 \text{ h}$ (though oscillations with a period of 5 min are clearly seen). If Hill's results arose from coherent oscillations of the solar surface it would be hard to explain the failure of the Nice group to see them, even if the Arizona results were partly a result of temperature variations.

The apparent discrepancy would be resolved if the variations detected by Hill *et al.* are the result of motions which are not coherent over the solar surface, so that they would be washed out in the Nice measurements. Indeed, the technique of Hill *et al.* would be particularly sensitive to motions with a coherence scale comparable with that over which they average.

Without going into the details of the apparatus of Hill *et al.*, we note that their slit length is $\sim 100''$, which corresponds to twice the supergranular scale of 30,000 km. Thus the results of Hill *et al.* represent an average over a few supergranules, whereas the Grec-Fossat measurements average over $\sim 1,000$. Appropriate motion in the supergranules could therefore explain the difference in results.

Supergranule motions are seen in the solar surface and look like convective cells, with upwelling in the centres and with horizontal outflow over most of the surfaces at speeds of $\sim 0.5 \text{ km s}^{-1}$ (refs 4, 5). These motions are distributed over the solar surface in a roughly polygonal network. At parts of the interface between the supergranules, vertical magnetic fields are observed with intensities of $\sim 1,800 \text{ Gauss}$ (ref. 6). These fields are concentrated in small spots which are located preferentially at the corners of the supergranules. Unfortunately, we have no direct knowledge of the field topology below the visible layers of the Sun. On theoretical grounds it is believed that these fields blend into a prevalent toroidal field well below the surface. Whether the observed flux ropes merge in relatively shallow layers or remain discrete over great depths is, however, not known.

Let us suppose the former possibility. Then the lower parts of the supergranules are partly separated by the magnetic field. Thus, we may consider the fluid in each supergranule to be loosely contained in a roughly fashioned, rather leaky cup. The cup walls would of course be flaccid, since the fields would probably be much weaker than the values observed in the small dots seen in the surface layers.

We propose that within these magnetic cups there occur seiches (slow sloshing motions). Such motion is well known to limnologists and is readily observed in a mug of beer held in an unsteady hand. The motion has little shear, and should therefore have low dissipation except in the very turbulent upper layer. At the speed suggested by the observations of Hill *et al.*, the supergranular seiches should be nearly incompressible. If we presume that the depth of a cup, h , is $\sim l$, the supergranular diameter, then the scale height near the bottom is $\sim h$; only in the upper layers do we face great inhomogeneity. We may therefore estimate the period P of the fundamental seiche mode using Merian's formula⁷

$$P = \frac{2l}{(gh)^{\frac{1}{2}}} = 11 \left(\frac{l}{h} \right)^{\frac{1}{2}} \text{ min}$$

where g is the solar surface gravity. Of course this is a very crude estimate, since a number of complicating factors have been ignored. In particular, the restraining effect of the magnetic field has probably been grossly exaggerated, and it is likely that the period should be considerably longer than this formula suggests. Nevertheless, Merian's formula gives some idea of the order of magnitude of the period if we know the value of l/h .

It has been suggested⁸ that supergranules are squat with $l/h \simeq 5$. The arguments for this are not compelling, and in fact we do not know why there should be such a distinct cell size in what appears to be a very turbulent layer. Moreover, we have to distinguish between the depth to which traces of the horizontal pattern persist and the depth we would attribute to a coherent

motion of the sort we are contemplating. The latter depth, which is h in our picture, is that at which the toroidal magnetic field becomes appreciable and is able to provide effective basins in which the supergranules may rest. If we suppose that the surface magnetic field is anchored in this toroidal field we can estimate this depth.

One might suppose that the depth dependence of the solar angular velocity Ω near the equator is such that the differential rotation maintains approximate neutrality according to Rayleigh's criterion. Then near the equator

$$\Omega \simeq \Omega_s \left(\frac{R}{r} \right)^2$$

where Ω_s is the surface angular velocity, R is the solar radius, and r is the radial co-ordinate. The value of Ω at the depth of interest is reflected by that of the sunspots and the magnetic network as seen at the surface. The difference between Ω and Ω_s is $\sim 5\%$ (ref. 4). This suggests depths of $\sim 2 \times 10^4 \text{ km}$. A similar argument has been advanced by Foukal and Jokipii⁹.

Thus we have estimates for l/h in the range 1–5 and Merian's formula suggests periods in the range of 10–30 min. The flexibility of the walls will raise these values, and periods $\sim 1 \text{ h}$ seem possible.

The way in which seicheing of supergranules could affect the results of the Arizona group is complicated. Slight tilting in a suitable direction of a supergranule at the limb could modify the local limb darkening, to which the Arizona observations are very sensitive, but it seems premature to enter into such details in this very tentative model. We note that the kind of effect we allude to here gives a change in the apparent position of the limb. It may also give some change in local intensity, but if this is appreciable, the picture we propose would appear to be ruled out by recent work of Musman and Nye who have failed to detect brightness fluctuations on the solar disk with periods in the range of 15–90 min. To illustrate the kind of effect we envisage, it may be adequate to adopt the simplistic view that seiches would make their presence known through slight local elevations of the 'solar surface'.

If speeds in the seiche mode are $\sim 10 \text{ m s}^{-1}$, the picture is compatible with the observations of Hill *et al.* and also predicts that the observations made in Nice would provide negative results unless the sensitivity were increased to detect velocities significantly $< 1 \text{ m s}^{-1}$ or unless the area averaged over were appreciably reduced. Moreover, the energy in the motion is much less than that required if the observations are to be explained in terms of nearly pure global normal modes, since the seiches are probably not very deep. This is satisfying in view of the recent computations by Goldreich and Keeley¹⁰, which indicate that it might be difficult to excite such modes in the Sun by turbulent driving. As to the excitation of the seiches, various possibilities present themselves. For example, supergranules last $\sim 40 \text{ h}$, according to Simon and Worden, and seiches would probably be excited as part of the formation process. In addition, undulations of the deep toroidal magnetic field would provide rocking of the magnetic cups, and consequent excitation of the modes.

The idea of sloshing supergranules is based on assumptions about the subsurface field topology. Where the surface field emanates from the underlying toroidal field there should be significant deformations, perhaps ridges, in the toroidal field. But it may be that these structures lie too deep to confine the supergranules. Nevertheless, individual motions of supergranules might arise, though the existence of an adequate excitation mechanism is then less apparent. Among the possibilities for exploration is the collective interaction of supergranules, as also noted by N. O. Weiss. This might produce suitable surface undulations, but it is not clear what the period would be. This would also provide some degree of phase coherence. Surface waves travelling at the local sound or gravity wave speeds do, however, traverse a supergranule in $\sim 1 \text{ h}$ and long waves of this kind would have nodes at the super-

We believe, therefore, that there are sufficient grounds for suggesting that one should study motions of supergranules as individual entities. The amplitude of the motion needed to resolve the apparent conflict in the present observations suggests that the seiches would be detectable. Indeed, there are observed variations in the solar surface which indicate that such motions may actually exist¹¹.

Note added in proof: Hill¹⁴ has recently found evidence for phase coherence of the 45-min oscillation over 30 d and Kotov *et al.*¹⁵ have found phase coherence of the 2 h 40-min oscillation over 3 yr. Thus although supergranular seiching and the passage of supergranules across the field of view may contaminate the measurements, the above evidence would imply that the oscillation data cannot be attributed entirely to these phenomena.

DIFFERENTIATION in silicate magmas is usually considered to occur through processes of fractional crystallisation. The possibility that the formation of a second silicate liquid, immiscible with the original silicate magma, may take place has been thought unlikely¹. But in lunar rocks textures were found indicating late-stage formation of a K₂O-rich silicate liquid², and serious consideration is being given to the possible importance of silicate liquid immiscibility³. Current investigations on the role of silicate liquid immiscibility were started with the work of refs 4 and 5. Because of the importance of the two-liquid field in the current developments we have re-investigated the K₂O-FeO-Al₂O₃-SiO₂ system. Electron scanning microscopy combined with electron microprobe analyses allowed us to delineate the extent of the two-liquid field as well as to determine the compositions of the two coexisting liquids.

buffer, which lies within the FeO stability field⁸. Runs were made at temperatures between 1,100 and 1,700 °C *in vacuo*. The samples were kept in molybdenum capsules.

The most interesting result of our study concerns the compositional range of the two-liquid field. It extends from the binary join FeO-SiO₂ to the stability field of leucite, (Fig. 1) and incorporates the two smaller separated fields found previously. This result is based on more than 150 runs at various temperatures. Runs with initial composition in between the two miscibility gaps found previously also produced two liquids. As an example two runs at 1,550 °C are shown in Fig. 1. Electron microprobe data show that the liquids are homogeneous, indicating that equilibrium was obtained. The co-existing liquids can be characterised as a FeO-rich liquid with a K₂O/Al₂O₃ ratio of ~ 0.6 and a SiO₂-rich liquid with a K₂O/Al₂O₃ ratio of ~ 1.

The run products show that the two liquids form droplets within each other, which has been considered as the classical proof for liquid immiscibility⁴. Figure 2a shows a typical example of textural features which were found in runs made at temperatures $< 1,250^{\circ}\text{C}$ and $> 1,400^{\circ}\text{C}$, the size of the droplets varies from 3 mm to submicroscopic. In runs at intermediate temperatures separation of the two melts occurs on a submicroscopic scale only. Examples of this type of separation are shown in a series of scanning electron micrographs, see Fig. 2 If the etched glass surface did not show a texture

Fig. 2 Photographs of run products. Initial compositions lie roughly on the 30% FeO isopleth. *a*, Thin section of a typical run at low temperature (1,150 °C) in the middle of the two liquid field. The bar is 200 μ m long. Black spheres of a FeO-rich liquid in a matrix of colourless SiO₂-rich liquid. Note the variation in size of the spheres; grey cloudy areas (upper left) indicate submicroscopic scale separation. Pictures *b-f* are scanning electron micrographs of etched surfaces of run products. The etching agent was HF which preferentially removed the SiO₂-rich liquid. The bar is again 2- μ m long. *b*, Sample from one liquid field. Run temperature 1,300 °C (normal image). *c*, Sample from two-liquid field, just inside the two-liquid/one-liquid phase boundary. Run temperature 1,300 °C. White droplets are the SiO₂-rich glass (inverted image). *d*, Sample from the middle of the two-liquid field. Run temperature 1,300 °C. Size of the droplets is larger than in *c* (inverted image). *e*, Sample from the two-liquid field, close to the FeO-SiO₂ join. Run temperature 1,300 °C. Spheres are the FeO-rich liquid. On the left hand is a tridymite crystal (normal image). *f*, Sample from the leucite + two liquid field. Run temperature 1,200 °C. Black spherical cavities indicate the SiO₂-rich glass removed by etching. On the right side is a leucite crystal (normal image).

indicating unmixing (Fig. 2*b*) the liquid was considered to be homogeneous. If droplets of one liquid were found in a matrix of another, clearly two liquids were present, and the run was considered to lie within the two-liquid field (Fig. 2*c-e*). These textures are typical for a spinodal phase separation mechanism⁷. The size of the droplets increases toward the FeO-SiO₂ join. Close to this join tridymite or cristoballite was found together with the two liquids (Fig. 2*e*). An example of leucite plus two liquids is shown in Fig. 2*f*.

The phase relations of the liquidus surface are shown in Fig. 1. The two-liquid field intersects the liquidus surface at 1,695 °C on the FeO-SiO₂ join. It extends into the system and reaches a minimum at 1,130 °C (B-B') where FeO-rich liquid reacts to form fayalite+leucite+SiO₂-rich liquid. Thus, any Fe₂SiO₇-rich liquid must produce SiO₂-rich liquids during the course of crystallisation, without the formation of liquids of intermediate compositions. An important reaction occurs at 1,150 °C (A-A'). At this temperature tridymite reacts with the FeO-rich liquid to form fayalite plus SiO₂-rich liquid. Fayalite coexists with the SiO₂-rich liquid down to the eutectic.

The geological importance of these new data is that at least for dry magmas an FeO-rich basalt must yield an immiscible granitic liquid during the later stages of

crystallisation. Liquids of intermediate composition are not formed in this process. The immiscibility textures in lunar rocks² are an example of this. On Earth, excellent immiscibility textures were found in Archean variolitic pillow lavas near Noranda (Quebec, Canada) by Gelinás *et al.*⁸. In conclusion, the suggestion that the granophyres found in close association with ferro-gabbroic rocks may be produced by a process of liquid immiscibility⁹, appears to be valid.

Phosgene in the ambient air

IN recent years the atmosphere has become contaminated with a large number of halogenated compounds. Whereas inert fluorocarbons are suspect as precursors of stratospheric ozone-destroying chlorine atoms, other halocarbons, such as vinyl chloride, chloroform and trichloroethylene, have been found to be carcinogens^{1,2}. We present here the first measurements of ambient phosgene (COCl_2), and demonstrate that chloroethylenes (primarily C_2Cl_4 and C_2HCl_3), which are emitted worldwide in extremely large quantities (1.5×10^6 t in 1975), photodecompose to form highly toxic species such as phosgene and chloroacetylchlorides. A consideration of the sources, the distribution, and the fate of these species suggests that a significant environmental impact is possible. The results presented here are based on laboratory and field studies conducted within California in 1976.

Phosgene is manufactured primarily for captive use, and its production in the United States in 1975 was in excess of 0.4×10^6 t. It is a highly toxic chemical, although very little is known about the health hazards associated with long term exposure to low concentrations of the gas³.

A special purpose electron-capture (EC) gas chromatograph (GC) equipped with two EC detectors in series was used for ambient phosgene analysis (Fig. 1). Calibrations were performed using a permeation tube and further checked in the field using the absolute pulse flow coulometric (PFC) method developed by Singh *et al.*⁴.

The phosgene was identified by comparing three independent properties, namely, GC retention data, the EC ionisation efficiency (Fig. 1), and phosgene destruction rates on glass surfaces with standard phosgene mixtures. The possibility of interference from other trace atmospheric halogenated species (such as CCl_3F , CCl_2F_2 , $\text{CCl}_3\text{FCClF}_2$, $\text{CClF}_2\text{CClF}_2$, CHCl_2F , CHClF_2 , CH_3Cl , CH_3I , CH_3Br , CH_2Cl_2 , CHCl_3 , CH_3CCl_3 , CCl_4 , C_2HCl_3 , C_2Cl_4 , $\text{CH}_2\text{BrCH}_2\text{Br}$, and SF_6) was eliminated by retention data measurements. The high ionisation efficiency of phosgene further precludes any possible interference, since only a few known species (such as CCl_4 , SF_6) are as good absorbers of electrons. An Ascarite trap in front of the GC column was able to remove phosgene as expected. A GC-MS confirmatory test was not possible because of the high liquid phase loading of the GC column and the unavailability of other acceptable column packings.

Field monitoring was conducted on a 24 h-a-day basis at four Californian sites (urban and non-urban) with the help of a mobile environmental laboratory. Table 1 provides the results of phosgene concentrations measured at these four sites, together with the concentrations of C_2Cl_4 and C_2HCl_3 , its suspected precursors. The range of phosgene concentrations

Fig. 1 Dual EC-GC chromatogram showing ambient phosgene elution for a 13.0-ml sample from Menlo Park. The separation was accomplished on a dual EC-GC, equipped with an aluminium column ($5' \times 0.25''$) packed with 30% didecyl phthalate on 100/120 mesh acid-washed Chromosorb P. This GC column was preconditioned with twenty, 5-ml injections of a 5 p.p.m. (10^{-6} v/v) mixture of phosgene and trichloroacetyl chloride in air. Both the GC column and the dual EC detector unit were maintained at 22°C . Ultrapure nitrogen (carrier gas) was passed through a sequence of traps containing charcoal, anhydrous calcium sulphate, and molecular sieve before entering the GC at a constant flow rate of 90 ml min^{-1} . All-glass syringes were used for sample injection, and the sample holdup time was kept < 15 s. The large peak is for fluorocarbon 11, retention time 6.9 min, p (ionisation efficiency) = 0.40; the small one is for phosgene, retention time 5.1 min, $p = 0.65$. The top curve is for ECD1, the bottom for ECD2, and the ionisation efficiency is given by $p = 1 - (\text{ECD2 signal/ECD1 signal})$.

was 13 to 61 p.p.b. (10^{-12} v/v) with a mean value of 21.6 p.p.b. at the remote site 3 which is $\sim 2/3$ the mean value of 31.7 p.p.b. in urban Los Angeles. This factor of 1.5 for the phosgene gradient between an urban and a remote site can be compared with a factor of 20 for its precursors. This primarily arises

§Maximum phosgene concentration.

because the precursors come from urban sources and are well dispersed by the time a significant decomposition to phosgene takes place.

The three readily identifiable sources of phosgene in air are: (1) direct emissions of phosgene during manufacture, handling, and use; (2) thermal decomposition of chlorinated hydrocarbons, and (3) photo-oxidation of chloroethylenes in the air. There are indications that the first two sources can result in a significant indoor hazard, but their contribution to the ambient budget is minimal. The photo-oxidation of chloroethylenes (C_2Cl_4 and C_2HCl_3) seems to be the most probable source of phosgene. Based on estimates from most recent laboratory studies⁵, present C_2Cl_4 and C_2HCl_3 emissions could result in the formation of $\sim 0.3 \times 10^6$ t of phosgene yr^{-1} . Because these solvents are typically emitted in urban areas and are relatively reactive (the tropospheric half lives of C_2HCl_3 and C_2Cl_4 are < 2 and 4 d, respectively), high concentrations of phosgene could be encountered during adverse meteorological conditions in and around urban centres.

The atmospheric sinks of phosgene are a matter of considerable uncertainty. The known absorption cross section of phosgene, and smog-chamber studies (where phosgene was found to be stable for 15 h under simulated tropospheric irradiations in the presence of 10,000 p.p.m. of water vapour) suggest negligible tropospheric loss through photolysis and gas-phase hydrolysis^{4,5}. The two important sinks of phosgene are heterogeneous decomposition and slow liquid-phase hydrolysis. The first sink is confirmed by the fact that phosgene at low concentrations was destroyed in contact with most surfaces within a few hours, and additionally, could not be measured in indoor spaces. During one day of field experiments, heavy overnight rain caused a 20% reduction in average phosgene concentrations. Slow dissolution in the ocean followed by hydrolysis is probably a significant sink of ambient phosgene. Other gas-phase reactions involving O and OH radicals are known to be very slow. It seems clear that phosgene is only removed slowly from the atmosphere.

Laboratory studies also suggest that the highly toxic di- and trichloroacetyl chlorides that are also formed from the photo-oxidation of C_2HCl_3 and C_2Cl_4 , respectively, would together be present at concentrations of about four times that of phosgene⁶. Methods for the measurement of chloroacetyl chlorides in the 10^{-1} – $1,000$ p.p.b. (10^{-12} v/v) range are not yet available. Secondary reactions of phosgene and chloroacetyl chlorides with ambient hydrocarbons and the heterogeneous decomposition of chloroacetyl chlorides to form chloromethanes have already been suggested⁶. It is also possible that cigarette smokers may be exposed to an additional dose of phosgene, especially in urban locations, since chloroethylenes are thermally decomposed to phosgene, and are often present at concentrations of up to 200 times the ambient phosgene concentrations.

Because of the high toxicity of phosgene and chloroacetyl chlorides, and the suggested carcinogenicity of C_2HCl_3 and its structural similarity to C_2Cl_4 , the continuous release of these chloroethylenes in such large quantities to the atmosphere may be undesirable.

This project has been financed in part with federal funds from the EPA.

Widespread late Quaternary aridity in Western Australia

UNTIL recently the only conclusive evidence of extended arid conditions during the late Wisconsin over the western part of the Australian continent, was largely provided by the submerged dunes of the Fitzroy estuary^{1,2}. This evidence has been used to support the concept of global tropical aridity during the late Quaternary³. From a study of the late Quaternary sediments of the coastal areas of Western Australia, however, it has become apparent that stable dune fields and sand sheets of late Quaternary age are found throughout this region (Fig. 1).

It is evident from electron microscope studies of quartz grain surface textures, and from the grain-size distribution and mineralogy of the sands, as well as from the field occurrence and form of the sand deposits, that these deposits must be aeolian in origin, and derived from inland sources. In the Fitzroy estuary Holocene marine sediments overlie dunes, and give these dunes a minimum age of 7,400 b.p. (ref. 2). Linear dunes in the Exmouth Gulf have been truncated by the same transgression. Further south, a minimum age is more difficult to establish. In the Geraldton area, an inset valley fill dated at $3,145 \pm 145$ b.p., consisting largely of reworked aeolian sands indicates that arid conditions, in that area, must have ceased by that time.

A likely maximum age for the aeolian deposits can be established from the age of red alluvial sediments from which some aeolian material was deflated. In the Geraldton region the red alluvial fill overlies deposits of the Sangamon high sea level of $\sim 120 \times 10^3$ b.p. (ref. 4). Carbonaceous

Fig. 1 The recognised extent of wind-blown sand deposits in the coastal areas of Western Australia.

material from the red alluvial fill gave a ^{14}C age of $> 37 \times 10^3$ yr. The considerable thickness of the red alluvial sediments in coastal sections demonstrates that they were deposited at a time when the sea level was considerably lower than at present. An early Wisconsin age seems plausible for the red alluvium, and hence it follows that this is the maximum age of the aeolian sands.

The stratigraphy of the deposits gives no additional evidence of the precise age of the wind-blown sands. Pedocalcic palaeosols from the Timor Shelf, dated at 17,000 b.p. (ref. 5), and lunette deposits in the South-west of Western Australia, with a corresponding age of $\sim 17,000$ b.p. (ref. 6), indicate, however, that at that time arid conditions prevailed both in the North and South of the state. This provides a possible age for the aeolian sands. More important than this is the fact that the combined evidence suggests the possibility that most of the western part of the Australian continent may have been intensely arid at that time.

Although the climatic conditions necessary to bring about widespread and intense aridity over most of Western Australia would require a fundamental alteration of the present climatic regime, the actual mechanisms which can bring about such conditions require only relatively minor changes in the present heat balance and circulation pattern of the continent. The present climate of Western Australia is dominated by the subsiding air of the sub-tropical high pressure belts⁷. The seasonal displacement of this belt brings about the two distinct precipitation regimes: summer rainfall in the North, through the incursion of moist tropical air; winter rainfall in the South, from mid-latitude depressions.

The travelling anticyclonic cells within the sub-tropical high pressure belt control both precipitation regimes. In winter this is especially so. In these months the anticyclonic cells become intense, enhanced by low surface temperatures, and move slowly⁸. In these conditions the anticyclonic cells can dominate much of the continent, and in Western Australia limit rainfall to the southern shores. In some instances a large anticyclonic cell may produce a blocking effect, deflecting mid-latitude fronts approaching the West Australian coast southwards, and restricting precipitation to the south-western corner.

Even during the summer months, the anticyclonic cells, which are now situated much further South, have a profound influence on the summer precipitation regime of the northern areas. Often, when an intense surface anticyclonic cell is present in the Australian Bight, stable conditions prevail in the lower troposphere over northern Western Australia. This stability occurs in spite of the presence of a shallow hot surface region low over the Pilbara Region. Only when the anticyclonic cell moves eastwards, or decays, will the stable conditions over the northern areas weaken, resulting in an increased likelihood of rainfall from monsoonal depressions and disturbances^{9,10}.

It is evident from the present climatic situation over the Australian continent that an increase in anticyclonicity would directly result in widespread aridity over most of the western portion of the continent. The lower global temperatures which prevailed at the time of the last glacial maximum would have been sufficient to bring about an increase in anticyclonicity. With a lowering of the July temperature by $\sim 5^\circ\text{C}$ (refs. 11, 12), the winter anticyclone would have become much more stable, and the frequency of breakdown of anticyclonic cells would have been considerably lower. As a result winter rainfall would have been confined to the extreme south-west with only occasional widespread rains over the southern half of the state.

During the summer months anticyclonic conditions would have been weakened but this may have been only to such

a degree that the mean synoptic conditions would have been similar to the present-day late spring or early autumn. In addition, because of a more restricted seasonal migration of the inter-tropical convergence zone, the summer anticyclonic cells would have been located further north than at present. These factors, combined with weaker Trade winds, would have resulted in extremely stable conditions, curtailing the amount and frequency of summer rainfall over the northern areas.

An additional factor which must be considered is that cooler sea surface temperatures may have greatly reduced the significance of the offshore waters of northern Australia as a tropical cyclogenetic area¹³. Tropical cyclones contribute a considerable proportion of the present total precipitation of the northern areas of the state (for example, at Port Hedland this accounts for 50% of the mean annual precipitation). A decrease in the frequency of cyclones, whether through reduced cyclogenesis or a more westerly sea path because of stable conditions prevailing over the continent, would drastically alter the precipitation amounts in the northern half of the state.

The circulation changes necessary to result in aridity prevailing over most of the western parts of the Australian continent are physically plausible from what is presently known of global climatic conditions at the last glacial maximum. With the changes in the circulation patterns that have been proposed to explain the geomorphological evidence, it is difficult to envisage that arid conditions could have prevailed in the tropics without intense aridity further south. This reconstruction also implies that arid conditions prevailed through much of the glacial periods, becoming especially pronounced at times of glacial maxima. Even today Western Australia is very susceptible to the onset of arid conditions, a present drop of 120 mm in the total annual rainfall would extend the present margins of aridity by some $473 \times 10^3 \text{ km}^2$ (ref. 14). It follows that the envisaged circulation conditions prevailing at the last glacial maximum would have had their most obvious manifestations in Western Australia. While this is only to be expected, the increase in anticyclonicity would have had an effect on the whole continent, to such an extent that these conditions are likely to have been the determinant of Australian climatic conditions through the glacial periods.

We thank Dr J. Gentilli for his help. Mr G. Kendricks gave us considerable advice, and Dr J. M. Bowler let us use, as yet, unpublished ^{14}C dates.

Evolution of ocean climate and the record of planktonic foraminifera

THE planktonic foraminiferal fossil record reveals two major evolutionary radiations, one in the Palaeogene and another in the Neogene. Preceding each radiation, at the beginning and middle of the Cainozoic, there were severe reductions in faunal diversity. Both reductions involved an elimination of tropical and sub-tropical forms and the radiations involved their restoration¹.

During the late Cretaceous and the Palaeogene (until about the Middle Eocene) faunas were diverse and well differentiated. Douglas² has shown that the late Cretaceous faunas, like modern ones, can be divided into cold- and warm-water groups (Boreal and Tethyan) and recently Szczuchura and Pozaryska³ have shown that the same is true for Palaeogene faunas. Both late Cretaceous and Palaeogene faunas, however, indicate a much greater expanse of warm water than exists today⁴.

In contrast, Danian and Oligocene faunas universally have a 'cold water' aspect. They are completely lacking in warm water morphotypes and diversities are consistently low. If subtropical or tropical pelagic habitats existed at the beginning or the middle of the Cainozoic, planktonic foraminifera give no clue to their whereabouts. Isotopic evidence indicates that the Oligocene was a cool period, possibly with glaciation at high latitudes⁵. More than that, however, the ungrouped faunas suggest rather structureless oceans that were not only cool, but lacking in the kind of climatic differentiation that exists now.

The Neogene radiation started at the beginning of the Miocene and by Middle Miocene there was a strong development of warm water forms. These forms, moreover, were widely distributed and, as in the Cretaceous and early Palaeogene, indicate a much greater expanse of warm water than exists today. The transition from Oligocene to Miocene cannot be dealt with now because of complex boundary questions. It is possible, however, to gain some idea of how modern plankton biogeography developed in the North Atlantic once warm water forms became re-established, by making faunal comparisons among several key areas around the North Atlantic Gyre.

The Mediterranean is a key area because it is stocked entirely from the eastern margin of the North Atlantic Gyre and its entrance is well north of the limits of the present Tropics. Since species are displaced to the south on the Ocean's eastern side, the Mediterranean is stocked with northern and subtropical forms but no tropical ones. The rare tropical forms that are found in the Mediterranean from Pliocene to Recent are not part of the indigenous fauna. On the western side of the ocean, displacement is to the north and tropical species are found as far north as 42°N, in the vicinity of the Gulf Stream⁶. Tropical forms are, however, abundantly represented in the Miocene Mediterranean, in particular, *Globorotalia menardii*, a modern tropical species with a geological record dating back to the Miocene. From its evolution in the Middle Miocene until the end of the Miocene, this species is common and continuously distributed throughout the Mediterranean and there can be no doubt that it was part of the indigenous fauna. It would seem therefore, that the Tropics extended much further north during the Miocene, at least to the vicinity of the entrance to the Mediterranean (36°N).

An alternative theory is a Miocene Tethyan seaway, with penetration of tropical forms from the Indo-Pacific. There is, indeed, much about Miocene planktonic faunas to suggest Tethyan relationships, but evidence from marine invertebrates seems to demonstrate convincingly that the eastern gateway to the Mediterranean was closed by about the middle of the Cainozoic^{7,8}.

Unfortunately, planktonic faunas from the western side of the North Atlantic are poorly known except for the tropical region where, of course, *G. menardii* is abundantly represented. The Deep Sea Drilling Project (DSDP) has, however, cored two

high latitude sites in the North Atlantic that have very important biogeographic implications. One site is on the western side of the ocean near Labrador (50°25'N), the other on the eastern side in the Hatton-Rockall Basin near the British Isles at 57°30' (ref. 9). The latter site yielded good late Miocene faunal assemblages that included *G. menardii*. Associated with *G. menardii* were the modern cold-water species *Globigerina bulloides* and *G. pachyderma* together with modern warm water, although not strictly tropical, species *Globigerinoides ruber*, *G. trilobus* and *Orbulina universa*¹⁰. This kind of mixed association is indicative of waters near the margin of the Gyre. The western drilling site near Labrador yielded a poor Miocene section, but faunal assemblages yielded warm-water forms¹¹. Also, early Miocene assemblages with close Caribbean affinities have been encountered near Nova Scotia¹².

These data, although sparsely distributed, indicate an expanded body of warm gyral water for the Miocene, the gyral limits extending perhaps 10° further north than they do now. Tropical limits probably also extended perhaps 10° further north than at present. This expanded warm gyral water persisted until the end of the Miocene, so it is unlikely that modern glaciation in the Northern Hemisphere began before the Pliocene.

Fig. 1 Clockwise displacement of tropical species in Pliocene and Recent. During the Miocene the northern limits of tropical forms extended much further north on the eastern side of the North Atlantic and E-W distribution may have been symmetrical.

At the end of the Miocene, the Mediterranean was completely closed and there was a 'salinity crisis'. Evaporation was widespread and thick deposits of salt accumulated over the abyssal plain of the entire basin¹³. Although this evaporation must have had a disruptive effect on planktonic faunas, it was of geologically short duration, because the faunal succession across the Mio-Pliocene boundary in the Mediterranean is almost complete. A major biogeographic change is, however, associated with this boundary because the Mediterranean ceased to be part of the tropical regime at the beginning of the Pliocene¹⁴. A lack of tropical forms is evident with the first Pliocene transgression following the 'salinity crisis', but although the possible connection with the salinity crisis is not clear, the coincidence of events seems remarkable.

The disappearance of tropical forms in the Mediterranean was not an isolated regional phenomenon; it was related to a general retreat of tropical forms on the eastern side of the North Atlantic. Tropical forms are also lacking in the early Pliocene sections of the cores drilled in the Hatton-Rockall Basin and the Bay of Biscay^{9,10}. At both those sites early Pliocene

assemblages are composed of a mixture of northern and subtropical forms. Tropical forms do occur in abundance in the core drilled south of the Mediterranean, near the Cape Verde Islands¹⁵. On the western side of the North Atlantic, however, tropical forms still extended much further north during the early Pliocene than they do today. In the core drilled near Labrador, Poore and Berggren¹⁶ recorded *Globorotalia menardii* and other tropical species from sediments no older than early Pliocene. Early Pliocene assemblages consist of a mixture of northern, subtropical and tropical species—a Gulf Stream type of association¹⁰.

These data are sparsely distributed but they clearly fit into a pattern that shows a modern type of dispersal of tropical species, with a strong clockwise northwards displacement on the western side of the ocean (Fig. 1)⁶. There are some intriguing implications, as follows: During the early Pliocene the tropical limit on the eastern side of the North Atlantic retracted to a position south of the Mediterranean entrance, probably close to where it is now. There was no 'cold wave' however, as warm gyral water persisted on the eastern side of the North Atlantic as far north as the Hatton–Rockall Basin (57°N). Early Pliocene assemblages there contain a good representation of subtropical species. Also, the western margin of the Gyre extended perhaps 8° further north than it does today, as indicated by the assemblages recorded in the Labrador core¹⁰.

The early Pliocene therefore, displays an intermediacy between Miocene and modern conditions and most likely represents a critical phase in the evolution of modern ocean climate and circulation. At this time, it seems, the expanded Miocene body of warm gyral water began to contract to modern proportions. What occurred in the early Pliocene was clearly the beginning of a long term condition. Although there have been numerous subsequent climatic fluctuations, there has never been a large enough expansion of warm gyral water to allow the establishment of tropical planktonic foraminifera in the Mediterranean or the higher latitudes of the North Atlantic.

I have omitted any reference to tectonic theory because it is not clear how plate movements would help resolve the questions at hand. Planktonic foraminiferal development displays a curious iterative pattern difficult to account for by unidirectional shifting of plates. For example, it could be argued that the broad expanse of warm water forms seen in the late Cretaceous and Palaeogene was due to an open Tethyan seaway which promoted dispersal from the equatorial region. Yet, a comparable expanse of warm water forms can be seen in the Miocene, when the Tethyan seaway was closed.

It seems that there have been long term cycles in the development of ocean climate and circulation, with alternating expansions and contractions of warm surface water. Expansions are visible in the late Cretaceous, Palaeogene and Miocene and contractions are apparent in the early and middle Cainozoic, which may have involved a complete eradication of warm gyral water. Another contraction seems to have begun in the early Pliocene but in this case there have been no signs of disintegration of warm gyral water, as both tropical and subtropical species have survived several glacial epochs.

Adaptation to an 8-h shift in living routine by members of a socially isolated community

THE proportion of the working population employed on some form of shift system has increased substantially over the past two or three decades. Expert opinion as to the optimal form of shift system is divided, however, between those who favour 'permanent' systems and those who favour 'rapidly rotating' ones. We have studied the adaptation of half the members of a socially isolated community to a permanent 8-h shift in their routine. Even in this seemingly ideal situation we failed to find complete adaptation of the ~24-h circadian rhythm in either body temperature or performance efficiency over the 10-d study period. This finding casts some doubt on the theory that permanent shift systems are optimal, and that the light–dark cycle is not important in entraining human circadian rhythms.

Circadian rhythms are now known to exist in most physiological parameters¹, and have also been found to affect the efficiency with which man performs various tasks². Performance speed on simple tasks, that place little reliance on short term memory, shows a rise throughout the day (with the exception of a more or less pronounced 'post-lunch decrement'³) and reaches a maximum at about 2000 (ref. 4). This rise parallels that found in body temperature. In contrast, the performance of more complex tasks, which rely heavily on short term memory, reaches a maximum rather earlier in the day⁵, and, with an exceptionally large short term memory load, has been shown to be negatively correlated with body temperature⁶.

In normal circumstances these rhythms are relatively constant from day to day, and are thought to be 'entrained' by a number of environmental *Zeitgeber* (cues) of which the most important seem to be the 24-h light–dark cycle and the 'social' environment⁷. There are, however, two fairly common situations in which man's circadian rhythms are disrupted, namely rapid transition from one time zone to another (the 'jet-lag' effect) and shift work. In the former case, the *Zeitgeber* in the new time zone seem to encourage the adaptation of the traveller's circadian rhythms to the new time zone, and complete adaptation of both temperature and performance rhythms typically occurs within about a

Fig. 1 The 'time since getting up' effect in urine flow temperature for the two pre-shift days (—) and for the 9th and 10th day of the shift period (---). 0, 4, 8, 12 and 16 h since getting up correspond to 0800, 1200, 1600, 2000 and 2400 for the pre-shift days, and to 1600, 2000, 2400, 0400 and 0800 for the shift period days.

week⁷. In the case of shift work, however, and in particular night shift, most *Zeitgeber* remain constant and thus discourage adaptation to the shift worked. Recent work⁸ has indicated that even after 12 successive night shifts (a rather greater number than are typically worked between rest days, during which shift workers normally revert to a 'day-time' routine) neither temperature nor performance is completely adapted to night work. Furthermore, readaptation to the normal routine during rest days seems to be very rapid and to occur within 2 or 3 d.

Fig. 2 The 'time since getting up' effect in *a*, manual dexterity and *b*, visual search for the two pre-shift days (—) and for the 9th and 10th day of the shift period (---). The points represent percentage deviation from the overall mean for the day in order to allow comparison between tasks.

'Permanent' night-shift systems, and slowly rotating shift systems that involve a number of successive night duties, thus result in the alternation of slow partial adaptation and rapid readaptation (during rest days) of man's circadian rhythms. In view of this, rapidly rotating shift systems (for example, two mornings, two evenings, two nights and two off) are recommended by some experts. These result in little disruption of the circadian rhythm, but result in the night work being carried out when performance, on at least simple tasks, is at low ebb. Others favour the idea of a permanent 'night subsociety' in which night workers would remain on an inverted routine even on their days off, and should thus be able to adapt completely to the night shift. This view assumes the social *Zeitgeber* to be rather more important than the light-dark cycle, and there is some evidence that this is the case⁷. It would, however, involve a considerable proportion of the population shifting the whole of their normal routine by, for instance, 8 h. This is in contrast to the present habit of most night workers who go to bed immediately after their work, and take their leisure time at the beginning of their waking day.

The present study took advantage of the complete social isolation, but normal light-dark cycle (sunrise ~ 0600, sunset ~ 1530 at the time of the study) that exist during the winter months at South Georgia. Six of the 12 members of

Fig. 3 The 'time since getting up' effect in *a*, arithmetic and *b*, verbal reasoning for the two pre-shift days (—) and for the 9th and 10th day of the shift period (---). The points represent percentage deviation from the overall mean for the day. In spite of considerable practice on these tasks before the study, there was evidence of a practice effect in the pre-shift results. The curves have been adjusted to take account of this using a linear approximation.

a British Antarctica Survey camp at South Georgia (54° 17'S, 36° 30'W) took part in the study. For ten successive days they shifted the whole of their normal daily routine by 8 h, so that instead of sleeping from 2400 to 0800 they slept from 0800 to 1600. For 2 d before, and for the last 2 d of, this 10-d period they undertook four tests of performance efficiency, and measured their urine flow temperatures⁹, at 4-h intervals throughout their waking day. Two of the performance tests used involved a negligible short term memory load: these were a 90-s visual search test involving a search through lines of upright Os for slightly tilted ones, and a manual dexterity test that involved exchanging nuts and bolts attached to two brass plates. The other two tests involved an intermediate memory load and were a 3-min test of verbal reasoning⁵, and a 5-min test of arithmetic².

Since the main concern of the study was whether or not there was complete adaptation (as opposed to some adaptation), the reference point used in the analysis was the time of getting up rather than clock time. If perfect adaptation had occurred there should be no difference in the 'time since getting up' effect from the two stages of the study. If, however, the opposing light-dark cycle, and the social influences of the six members of the camp who did not shift their routine, had prevented complete adaptation then this effect from the two stages should differ.

Considerable adaptation of the temperature rhythm took place, since the two curves in Fig. 1 are not too dissimilar. Indeed, there was an overall 'time since getting up' effect (Anova $P < 0.001$), but there was also evidence that this effect differed for the two stages of the study ($P < 0.025$). Deviation from perfect adaptation at the end of the shift period took the form of a reduction in amplitude, an earlier peak, and the lack of a predictive drop before the sleep

period. As such, it is very similar to that found in earlier shift studies^{7,8}.

The two low memory load tests, manual dexterity and visual search, showed a similar, but somewhat smaller, lack of adaptation (Fig. 2). Although there was no reduction in the amplitude of the 'time since getting up' effect, performance on both tasks reached an earlier peak and failed to show a drop before sleep at the end of the shift period. Again, considerable adaptation had clearly occurred, and only in the case of visual search was there evidence that this adaptation was incomplete ($P < 0.025$).

The two intermediate memory load tasks showed even better adaptation (Fig. 3), and for neither task was there any evidence that the adaptation was incomplete ($P > 0.25$ in both cases). Performance on both tasks reached an early peak 4 h after getting up, and a second peak 8 h later. This double peak has not normally been found⁴, although it has been noted before with an intermediate memory load task⁶. It seems to represent a composite of the early peak shown by pure short term memory tasks, and the late peak shown by simple tasks. The slightly more exaggerated 'time since getting up' effect that these two intermediate load tasks showed at the end of the shift period may be due to partial sleep deprivation. As is typical for night workers¹⁰, some of the present subjects complained of their inability to sleep properly during the shift period, and there is some evidence that sleep deprivation results in more marked daytime effects³. The reason such an exaggeration was not found in the simple tasks may be because such tasks are generally less prone to sleep-deprivation effects¹¹.

The conclusions to be drawn from these results are, in general, very similar to those based on studies where the subjects have not been members of a socially isolated community⁸. Even after ten successive days of an 8-h shift, complete adaptation had not occurred in either temperature or visual search performance. Although the other performance measures showed no significant lack of adaptation, it is generally accepted that different rhythms adapt to a time shift at different rates⁷, and the adaptation of performance rhythms may well be quicker than that of the physiological ones. The lack of complete adaptation could be due to the social influences of the six members of the camp who did not shift their routine, and/or to the opposing light-dark cycle. Although it has recently been suggested that the light-dark cycle is relatively unimportant for man⁷, this is based on results using only an artificial light-dark cycle. It is quite possible that the natural cycle is a rather stronger *Zeitgeber* than these studies would suggest, especially since in the present study the contact between the shifted and unshifted members of the camp was minimal.

D.G.H. thanks his colleagues in Antarctica for their willing help and cooperation in this project.

Short term increases in mortality during heatwaves

COMPARISON of the weekly death registrations in Greater London¹ with temperatures at the London Weather Centre during the summer of 1975 shows a temporary increase in mortality that coincides with the heatwave of late July to mid-August (Fig. 1). There was also an increase in death registrations in the first week of June, when there was a change from cold weather with a little snow to very warm weather (but these figures may have been slightly inflated by increased delays in registration following a public holiday in the previous week). Increases in mortality associated with heatwaves have been widely reported in North America, although there is some evidence that the pattern there may have been modified by air conditioning²⁻⁵. Little attention has been drawn to such episodes in England and Wales, although an association between deaths from cerebral infarction and temperature in summer has been reported⁶.

The hot weather during the summer of 1975 was exceptional, yet similar conditions were again recorded in 1976 (Fig. 2). During the heatwave in late June and early July, temperatures were marginally higher than in 1975. Again there was an increase in weekly death registrations in Greater London, predominantly among the over-65 age group. This heatwave affected much of the country; attention has been drawn to a parallel rise in deaths in the remainder of south-east England⁷, and mortality increased for England and Wales as a whole. There was also a small increase in deaths in early May (Fig. 2), when temperatures were high for the time of year. The reduced number of registrations in the week ending September 2 was probably attributable to delays following the public holiday in that week; any similar tendency in 1975 may have been obscured by the further rise in temperature that occurred then.

There are clearly many difficulties in the interpretation of short term changes in mortality based on weekly registration records. This is particularly true in relation to the effects of hot periods, which in England are usually short, although some other major episodes (in 1974 for example), have been associated with marked increases in weekly totals. For a period of hot weather in 1968, however, death totals for Greater London, tabulated by date of occurrence, have been provided by the Office of Population Censuses and Surveys, as part of a general arrangement for a larger study of the effects of environmental factors on mortality (A.M. unpublished). Figure 3 shows the death totals together with daily temperatures measured at London Airport (Heathrow) for this period. Weather data from Heathrow were selected for the main study because of their availability on magnetic tape.

The hot period at the beginning of July was comparatively short lived, and it was associated with warm air currents from the Sahara, which brought an unusually warm night (minimum 20 °C), during which a layer of red dust fell over much of southern and eastern England. This was followed on July 1 by an exceptionally warm day (maximum 32 °C), and another warm night. Similar temperatures were recorded at the London Weather Centre and elsewhere within and beyond Greater London. Mortality increased sharply on July 1 and remained high on the following day. Increases were seen in cardiovascular

Fig. 1 Weekly totals of deaths registered in Greater London, by age, and weekly maximum (a) and minimum (b) temperatures (London Weather Centre), for summer 1975.

and respiratory causes of death, and in the total of the remaining causes. It is unlikely that the dust associated with this heatwave had any direct effect on mortality. No complete study of the particle size distribution of the dust in suspension was reported, but the mass median diameter

of deposited particles was found to be $9\text{ }\mu\text{m}$ in a study in Hull⁶. This is consistent with unpublished results obtained in London, and these findings indicate that much of the material was too coarse to be inhaled deeply into the lungs.

Fig. 2 Weekly totals of deaths registered in Greater London, by age, and weekly maximum (a) and minimum (b) temperatures (London Weather Centre), for summer 1976.

Fig. 3 Daily totals of deaths occurring in Greater London, by age, and daily maximum (a) and minimum (b) temperatures (London Airport, Heathrow) for summer 1968.

An analysis by age at death is included in Fig. 3. Increases in mortality were seen both in the 60–74 and 75+ age groups, but here the two have been combined for clarity of presentation. There was no sign of any increase in mortality in the 0–4 age group (unfortunately it was not possible to subdivide this group retrospectively), in contrast to findings in the United States of increases in infant mortality during heatwaves. The number of deaths per day in this age group in Greater London is, however, very small; it would probably have been necessary to obtain data from a larger population to detect any significant increase in infant mortality.

In other years since 1968, associations have been seen between rises in temperature and increases in daily mortality in the summer months on occasions when the meteorological changes were less dramatic than those described here, and the increases in mortality were smaller; indeed, they were not evident in the weekly death registration totals, and only became evident when the daily totals were examined. This work will be reported in detail elsewhere.

Mycorrhizal fungi stimulate clover growth in New Zealand hill country soils

VESICULAR-ARBUSCULAR mycorrhizal fungi infect most higher plants and usually increase plant growth and phosphorus uptake, especially in infertile soils¹. Mosse^{2–4} has shown that the indigenous mycorrhizal fungi in some soils are very infective but much less efficient in stimulating phosphorus uptake and plant growth than selected mycorrhizal fungi maintained in glasshouse pot culture. New Zealand soils have a short history of pastoral agriculture (<150 yr) and still range in fertility from very phosphorus-deficient podocarp–broadleaf forest soils to well developed and highly fertile pasture soils. Most hill country pastures consist of introduced grasses and legumes which are invariably mycorrhizal^{5,6}. These pastures have been developed within the past 100 yr from infertile forest soils in which nearly all plants were mycorrhizal⁷ and many were completely dependent on mycorrhizal infection for phosphate uptake and plant growth^{8,9}. Many forests are still being cleared and brought into pasture by oversowing with white clover and spreading heavy dressings of superphosphate. It is important to know whether the indigenous mycorrhizal fungi adapted to these infertile forest soils are as effective at stimulating clover growth in highly fertilised pastures as an efficient mycorrhizal fungus such as *E₃* (ref. 10), a *Glomus* species from Mosse's Rothamsted collection.

*All soils sterilised.

†Measured by modified Truog test¹².

‡Soil from broadleaf forest.

¶Soil from recent or rough pasture.

§Soil from well developed pasture.

Data analysed by analysis of variance after log transformation. When the ratio of any two shoot DM means \geq LSR (least significant ratio), the means are significantly different at $P = 0.05$.

Accordingly, samples of 37 hill country soils were collected in the North Island of New Zealand, in several instances from adjacent forest, recent pasture and well-developed pasture sites on the same soil type. Soils were sieved and most of the sample sterilised with methyl bromide to kill the indigenous mycorrhizal fungi. Most soils had a pH between 5.2 and 5.8. White clover was grown from seed in the unsterilised portion of each soil and at intervals seedlings were harvested and their roots cleared and stained to assess the speed of infection of the indigenous mycorrhizal fungi.

In three infertile forest soils (Waingaro steep land, Waitakere hill, Patua loam) clover roots were only 12, 2 and 1% mycorrhizal 15 d after seed germination, but infection levels gradually rose to 40% after 43 d. In two other forest soils (Autea clay, Burrell sandy loam) the indigenous fungi also infected very slowly with only 6–11% of the roots mycorrhizal even after 43 d. In all the remaining soils, including the Waitakere, Patua, Autea and Burrell soils from under well developed pasture, the indigenous mycorrhizal fungi in the pasture were very infective, with 30–90% of clover roots mycorrhizal within 15 d of seed germination. It is apparent therefore, that during the change from forest to pasture, soils not only become more fertile (Table 1) but their mycorrhizal fungi infect clover more rapidly.

In each of the 37 soils, clover was grown from seed for one month in the unsterilised portion, and seedlings became infected with the indigenous mycorrhizal fungi. Seedlings were then transplanted two per pot into 10-cm pots of the same soil which had been sterilised.

For comparison, seedlings which had been raised in E_3 -infested sterilised soil and control seedlings in sterilised soil with no added fungi were also transplanted into pots of each sterilised soil. Twice filtered washings from all unsterilised soils were added to the pots to ensure that all plants received the same microflora apart from mycorrhizal fungi.

All plants were inoculated twice with *Rhizobium trifolii* strain TA₁ and received weekly applications of nutrient solution containing all essential elements except N and P. This ensured that P alone was limiting growth. There were four replicate pots of each of the 111 treatments (37 soils \times 3 mycorrhizal regimes) randomly arranged and the experiment ran for eight weeks in a shaded glasshouse.

Tables 1 and 2 show that most of the indigenous mycorrhizal fungi were quite efficient and greatly increased growth over controls, especially in the infertile forest soils in which responses were up to 38-fold (Te Pari silt loam, 12 p.p.m. P, Table 1). In all but four soils, 30% or more of the root system was mycorrhizal.

In Burrell sandy loam (forest, 16 p.p.m. P) however, the indigenous fungi had only infected 8% of clover roots and mycorrhizal plants were smaller than controls. In Autea clay (forest, 12 p.p.m. P), the indigenous fungi had managed to infect 39% of clover roots, but were very inefficient and hardly increased shoot DM over controls. In both these soils, inoculation with E_3 led to massive increases in shoot dry matter (DM) (Table 1). In the other three forest soils in which the indigenous mycorrhizal fungi had been initially slow to infect, root infections were high and growth responses to indigenous mycorrhizal fungi were large.

Although the response to mycorrhizal infection decreased as soil fertility rose (Tables 1 and 2) the indigenous mycorrhizal fungi were still beneficial in most of the fertile soils, with a growth response of 39% occurring in Burrell sandy loam from pasture (120 p.p.m. P, Table 2). In five soils, the growth responses to the indigenous mycorrhizal fungi were not significant at the 5% level although they followed the general trend.

In 24 soils, including most forest soils, E_3 was more efficient than the indigenous mycorrhizal fungi at increasing plant growth (Table 1). E_3 infection caused 1,940% more plant growth than the indigenous mycorrhizal fungi in Burrell sandy loam from under forest (16 p.p.m. P, Table

Table 2 Hill country soils* in which the indigenous mycorrhizal fungi were more efficient than E_3

*All soils sterilised.

‡, ¶, § as in Table 1.

1), and in excess of 100% more growth than the indigenous fungi in seven other soils, and 30% more growth in a total of 20 soils (Table 1).

The efficiency of a mycorrhizal fungus at increasing plant growth was not related to the percentage of host roots it infected. For example, in Taihape silt loam the E_3 -infected plants had 55% of roots mycorrhizal and a mean shoot DM of 242 mg, while plants infected with the indigenous mycorrhizal fungi had 73% of mycorrhizal roots but only 65 mg shoot DM. For most soil types, the increased efficiency of E_3 over the indigenous mycorrhizal fungi was greatest in the forest soil, but in Te Pari silt loam, the reverse was true.

In 11 soils the indigenous fungi were more efficient than E_3 (Table 2), but in only four soils (Te Kuiti, Whangamomona, Patua and Mahoenui) was the increased growth greater than 30%.

In conclusion, it is apparent that clover is highly dependent on infection by mycorrhizal fungi for growth in many hill country soils. The extra benefit from E_3 over the indigenous mycorrhizal fungi achieved in such a wide range of soils is very promising, and field inoculation may be feasible if E_3 can be established in natural soils in the face of competition from the indigenous but less efficient fungi already present. Mosse⁴ has already demonstrated this in some British soils.

I am grateful to Mr Jack Park and Mrs Jeanette Daniel for technical assistance, and Mr M. B. O'Connor for selecting suitable soils.

Protozoa as sources of antigen in 'humidifier fever'

IN the field of hypersensitivity reactions to inhaled materials, sources of antigenic production are as varied as avian protein, pituitary stuff, wheat weevil, *Aspergilli*, and thermophilic actinomycetes¹. We have found a completely new group of organisms

which give rise to antigens associated with 'humidifier fever'²—one of the diseases in the extrinsic allergic alveolitis group¹. The organisms are amoebae that develop in the recirculating water used in the humidification systems.

The ubiquitous nature of these Protozoa suggests that sensitisation to them or their products may not be confined to the groups of individuals already studied, and that industry should be made aware of the possibility of the development of these organisms in stagnant or recirculating water, particularly when processes release material upon which microorganisms can develop into the environment.

Our attention was first drawn to the problem when about 20 of 50 office staff were reported as having pyrexial episodes, often with myalgia, some hours after leaving the factory, and usually on a Monday. The office adjoins the factory which uses a humidifier for plant heating as well as for one of its industrial processes. Moreover, above the office is a suspended ceiling on which dust from the factory has accumulated.

Such episodes have been recorded previously as 'humidifier fever'² or as hypersensitivity pneumonitis attributable to air conditioner contamination,³ although the clinical manifestations are not necessarily identical with those we have found.

It is considered that contamination of the humidifiers by organisms, and the release of these or their products into the environment is responsible for sensitisation and subsequent disease⁴. The source of antigens has been described as a member of the *Micropolyspora* genus³ (now identified as *Thermoactinomyces vulgaris*—J. Salvaggio, personal communication), *T. vulgaris*⁴ or thermotolerant bacilli⁵. Lines of precipitation have been recorded against *T. vulgaris* with sera from affected individuals⁴, and inhalation challenge tests using *T. vulgaris* have produced a pyrexial episode^{3,4}. However, some *T. vulgaris* strains can produce materials capable of reacting nonspecifically with human sera⁶, as can material from *Staphylococcus aureus*⁷ and the so-called byssinosis 'antigen'⁸. Apart from this possibly 'false positive' reaction, serological testing with extracts of other organisms has been without success^{9,10}, although lyophilised water from the humidifier may contain materials capable of reacting with sera of affected individuals¹⁰.

Our studies involved isolating organisms from the atmosphere of the office, the dust on the false ceiling, and from the humidifier. Many fungi and bacteria were isolated, identified, and extracts were tested against sera from affected individuals. Apart from one or two weakly reacting extracts, results were negative on gel diffusion, although extracts of the 'ceiling dust' and material from the humidifier baffle plates reacted strongly with the sera of 16 of 18 affected individuals and 2 of 18 unaffected individuals working in the office ($P < 0.001$).

When material from the baffle plates was viewed microscopically it became apparent that Protozoa were present in abundance. Isolation provided two main groups of

Protozoa—ciliates and amoebae. Purified ciliates failed to produce antigenic material that reacted with sera from affected cases, whereas amoebae produced up to five precipitin lines. A named amoeba, *Naegleria gruberi* was obtained (Culture Centre of Algae and Protozoa, Cambridge), and grown in monoxenic culture with *Klebsiella aerogenes*. The resulting extract was antigenic, and the gel diffusion reaction indicated antigenic identity with material in the ceiling dust (Fig. 1). Amoebae isolated from the ceiling dust produced a similar result; *K. aerogenes* extract was weakly positive.

Fig. 1 Gel diffusion reaction: +, pooled sera from affected cases; S, saline; CD, ceiling dust extract; BM, Baffle plate 'muck' extract; KA, *Klebsiella aerogenes* extract; NG, *Naegleria gruberi* extract; CD and BM were aqueous extracts of ceiling dust and baffle plate muck concentrated and dialysed.

N. gruberi was grown for 7 d at room temperature on non-nutrient agar streaked with live *K. aerogenes*¹¹ and the plates extracted with 1% aqueous phenol, then concentrated and dialysed. *K. aerogenes* was prepared by the same method as *N. gruberi*. Note the join of the line from *N. gruberi* and CD indicating antigenic identity.

Thus, we believe we have been able to determine a source of antigens associated with 'humidifier fever' that has hitherto remained unrecognised; possibly one species of amoeba, that is, *N. gruberi*, will not provide all the antigens to which affected cases respond serologically; indeed, our current work suggests that several amoebae are present. We hope to assess the individual contribution of each of these to the overall antigenic picture.

We are indebted to Drs A. Jones and G. Westhall of the E.M.A.S. for first bringing the cases to our attention, and to Dr A. Axford for his help in clinical epidemiology. The photographic expertise of D. Llewellyn is appreciated.

Suppression of murine lupus erythematosus by Dactinomycin

THE disease of the NZB×NZW/F₁ hybrid mouse (B/W) is a model of systemic lupus erythematosus (SLE), perhaps the most autoimmune of human diseases. The animals develop LE cells and anti-nuclear antibodies of various specificities, and die of a fulminating chronic glomerulonephritis at an early age¹. Abnormalities of the skin² and central nervous system³, also reminiscent of clinical SLE, are present as well. Like SLE patients, many of the mice have greatly extended lifespans under treatment with corticosteroids, azathioprine or cyclophosphamide, or combinations thereof^{4,5}. There is a body of evidence⁶ which suggests that aberrant availability of autoantigens may be a factor in both SLE and B/W disease. Other groups have emphasised the availability of nuclear materials from keratinising skin cells as a source^{6–8}, but it seems to us that the nuclei from maturing erythrocytes should also be considered. All of the immunosuppressive agents mentioned above suppress erythropoiesis in mice⁹ and may also be limiting access of

Fig. 1 Longevity of Dactinomycin-treated NZB/NZW mice to 405 d. Control deaths began at about 6 months of age, and the last control died at close to 12 months. The cut-off on the graph was arbitrary, but all treated mice were alive beyond 450 d.

antigen to immune complexes. Here we show that Dactinomycin (actinomycin D), which inhibits erythropoiesis at doses which do not suppress antibody formation (ref. 9 and unpublished observations), is nevertheless an effective suppressant of B/W mouse disease.

In the present series female B/W mice were treated with Dactinomycin, beginning with a small daily dose, 0.35 μg subcutaneously, at about 3.5 months of age, increased to 1.8 $\mu\text{g d}^{-1}$ about 6 weeks later and doubled to 3.5 $\mu\text{g d}^{-1}$ a month after that, at about 6 months of age. The adjustments reflected significant reticulocyte counts in most of the treated animals. Weight was checked twice weekly; and

haematocrit, reticulocyte count, and urine protein every 4–5 weeks. The drug was stopped when weight loss was consistent in the group; treatment was suspended for an average of 5–6 d a month. Post-mortem tissues were fixed and snap-frozen for light and fluorescence microscopy.

At the present time, all 11 Dactinomycin-treated animals are alive at 14 months of age or more, mean 455 d (range 444–460), while all 11 age-matched control animals have died at a mean age of 256 d (range 189–358 d). Figure 1 illustrates the longevity data to 405 d. The difference is significant by the sign test ($P < 0.001$)¹⁰ and by the Mann-Whitney test ($P < 0.01$)¹¹. The treated animals have generally had low (or no) reticulocyte counts, but have maintained haematocrits at 40 or above. Urine protein at 14 months of age was 2+ and 3+ in single animals, but less in the other nine.

Fig. 2 Urine protein (-----) and haematocrit (——) in matched Dactinomycin-treated (●) and control (○) mice. The control animals died *a*, at 215 and *b*, at 230 d of age. The inverse relationship of haematocrit and urine protein is commonly seen in untreated animals. Haematocrits of treated animals have rarely been below 40, or urine protein above 2+. These trends continue.

Figure 2 illustrates the course of two age-matched pairs of animals, treated and untreated, from 3 to 9–10 months of age. Both show the stability of haematocrit and urine protein levels in the Dactinomycin-treated mice, and the inverse relationship of urine protein and haematocrit in the control animals. All untreated animals had heavy proteinuria before death and eight out of 11 had anaemia. Post-mortem renal tissue was evaluated by two observers without knowledge of source, and was judged 3+ or 4+ in severity in all the control animals. Granular staining of immunoglobulin and complement was seen in the glomeruli, with abundant mesangial deposition in most instances and varying amounts of glomerular loop staining. Both the light and fluorescence microscopic findings were typical of our experience in other series.

It seems from this initial group that Dactinomycin alone may suppress B/W disease as well as cyclophosphamide does and probably better than corticosteroids or azathioprine or both. Though a little unkempt in appearance because of loss of hair at injection sites, the animals are in a good condition, with mild or less proteinuria, at well over a year of age, and we plan to continue treating them for their remaining lifetimes.

The majority view of B/W disease today probably includes the following elements: inability to develop or sustain immunological tolerance¹; diminished cell-mediated immunity, following early loss of suppressor cells^{1,4}; and activity of both the Gross and FMR (Friend–Moloney–Rauscher) oncornavirus group^{1,4,12,13}. There has been little evidence that Dactinomycin facilitates tolerance induction¹⁴; in fact, Claman *et al.*¹⁵ found that Dactinomycin administration to mice converted soluble bovine gamma globulin from a tolerogen to an immunogen. In the few studies of cell-mediated immunity in Dactinomycin-treated

animals, responses were neither suppressed nor enhanced^{16,17}. Dactinomycin does have profound effects on the early phase of both Friend and Rauscher leukaemia^{18,19} at the same doses which inhibit normal erythropoiesis, presumably reflecting diminished numbers of erythroid target cells rather than direct effects on the viruses²⁰.

Another possibility is that combination of Dactinomycin with DNA inhibits reactivity with antibody to DNA. There are data suggesting that this is unlikely: Carr *et al.*²¹ developed an assay for human antibody to DNA which employed labelled Dactinomycin–DNA as antigen. They explicitly ruled out any influence by the intercalated Dactinomycin on reaction with antibody.

Although our data indicate that we have suppressed both erythropoiesis and B/W disease by Dactinomycin administration, other mechanisms cannot be ruled out. Immunosuppression, immunopotentiality, anti-viral effects, and interference with antigen–antibody combination have been mentioned, and there may well be others. On the basis of what was known, the profound influence on B/W disease was unexpected, and it suggests that re-examination of the therapeutic potential of Dactinomycin is warranted.

Our mouse colony originated from stocks held at the University of Minnesota, Minneapolis, Minnesota. Merck, Sharp and Dohme donated Dactinomycin. We appreciate the assistance of Miss June Smith, Department of Laboratory Medicine and Pathology, in setting up our facility and training our personnel. We thank Mr Ulrich H. Rudofsky and Dr Rodrigo E. Urizar for reviewing the histology, and Mr Andrew D. Simmons for his assistance with the immunofluorescence microscopy.

Hyperplastic nodules after portacaval anastomosis in rats

FOCAL proliferative or hyperplastic regions of liver cells are readily recognised in human liver diseases^{1,2} and there is a possibility that some types of hyperplastic nodules are important for the development of liver cancer³. The case for the precancerous nature of hyperplastic nodules however, rests entirely on data derived from chemical hepatocarcinogenesis and it is striking that toxic chemicals which are

not known to lead to cancer do not induce hyperplastic nodules, whereas almost all hepatic carcinogens do give rise to nodules¹. It seems of interest therefore to report the regular development of hyperplastic nodules in rats subjected to portacaval anastomosis without the addition of a known carcinogen to the diet or drinking water.

Male white rats bred in the Sutton Bonington Agricultural Unit, University of Nottingham, were maintained on Diet 41B supplied by Lillico Ltd. They were subjected to portacaval anastomosis (PCA) or sham operation² under ether anaesthesia at 150–200 g and housed six to a cage, on wire grids after the second postoperative day. PCA animals in groups of seven and controls in groups of three were killed after 1 week, 6 weeks, 2, 4, 6, 9 or 12 months. A further six rats were killed at 18 months and six were subjected to partial hepatectomy at 12 months and killed 5–8 months later. Apart from two PCA and one control rat in the first seven groups which were kept for glutaraldehyde perfusion, the liver of each rat was suspended in formol-saline and thin slices were fixed also in formol-alcohol. Dye was injected into the spleens of two controls, two 4-month PCA and three 6-month PCA to check for the presence of a collateral portal flow into the liver³.

Fig. 1 Hyperplastic tissue extending beyond inferior surfaces of liver 4 months after PCA. Pattern elsewhere regular ($\times 4$).

The animals recovered quickly from the operation and body weight was reduced for about a week, after which the weight gain paralleled that of controls. Liver weights were consistently lower (mean approximately 2% of body weight compared with approximately 3.5% in controls). The anatomical markings were more distinct after 1 week and by 6 weeks the liver surfaces were mottled dark and pale pink. These contrasting markings were accentuated by the second month and although many pale regions were regular but convex by 4 months, confluent foci were found and measured up to 1.0 cm in diameter (Fig. 1). By 6 months such hyperplastic foci varied in size and were found in all PCA animals; in two out of seven animals, masses extended beyond the borders of the median or anterior lobes of the liver. By 12 months, in every instance, the borders and surfaces of the livers were distorted by pale irregular hyperplastic regions, and masses, sometimes polypoid, projected into the peritoneal cavity (Fig. 2). Markedly irregular nodularity was striking after 18 months (Fig. 3).

Microscopy showed that the foci at first consisted of parenchymal cells which contained normally arranged vessels separated by atrophied cells in the perivenous regions, with evidence of compression by 6 months and loss of normal vascular relationships at 12 and 18 months (Fig. 4). Foci of crowded cells were noted, but no unequivocal malignant transformation was detected. Early

Fig. 2 Much distortion of liver surface by hyperplastic tissue, with nodule on inferior border of median lobe. Pattern elsewhere irregular. 12 months after PCA ($\times 2.3$).

changes were found in all experimental animals but not in controls and later changes with obvious distortion were noted to a lesser or greater extent in all PCA animals. Although adhesions were found quite frequently, portal revascularisation was not demonstrated on dye injection. The changes were more marked in animals subjected to partial hepatectomy in addition to portacaval anastomosis.

These experiments form part of an investigation into the reactions of atrophied hepatocytes. Such atrophied cells are known to undergo hyperplasia after the sudden reduction of hepatic tissue effected by partial resection in the PCA rat⁷. It therefore seemed possible that the rather slower, but nonetheless substantial, loss of parenchyma inherent in the response to the uncomplicated PCA also might effect a stimulus to hyperplasia. Such hyperplasia as occurred in this series seemed to involve at first predominantly periportal cells and it is not clear what part such anatomical

Fig. 3 Large nodule formation in liver remnant 18 months after PCA and 6 months after partial hepatectomy ($\times 2.3$).

zation might play in the ultimate development of hyperplastic nodules. The appearance of the hyperplastic nodules is similar to those induced by chemical carcinogens, but it is not yet known whether similar changes in biochemical properties and the antigenic complement of the hepatocytes occur^{3,4}. It would clearly be of major interest to ascertain whether a preneoplastic antigen is detectable in these circumstances³.

Fig. 4 Irregular hyperplastic nodule with compression of adjacent parenchyma and distortion of hepatic plates, taken from liver shown in Fig. 3. Haematoxylin and eosin ($\times 33.6$).

It is puzzling that these changes have not been mentioned previously^{6,8-10}. Most papers report that the microscopic appearances of livers from PCA rats are remarkably normal and that it is difficult to distinguish these from control livers. Microscopy of the present series confirms this superficial impression in early cases and, for the most part, vascular relationships are retained and plates of hepatocytes are flanked by sinusoids with a good complement of littoral cells^{6,9}. It is only when a comparison is made with macroscopic appearances that the irregularity, which is much more striking macroscopically and sometimes difficult to define microscopically particularly before 6 months, can be identified. After longer periods the compression of these foci on adjacent parenchyma is clearer and eventually the vascular pattern is much distorted, but this is a late phenomenon. At this stage, microscopy is revealing but only if the relevant part is selected. It seems possible therefore, that the changes described may easily not be noted unless gross examination is combined with microscopy.

Other possibilities include strain differences in the rats, housing and dietary effects. Strain differences are difficult to evaluate but in common with most other colonies none of our controls showed evidence of a tendency to nodule formation and at least one report refers to a similar strain⁶. Animal housing is relevant to the well-being of the experimental animals¹¹ and wire-bottomed cages much improve the clinical state of the rats, but there is no suggestion in this or any other work that this form of caging is conducive to nodule formation. It is difficult to see how the reduction in coprophagy might effect an increased rate of DNA synthesis, by pathways involving a reduced B₁₂ metabolism or any others. With regard to the possibility of dietary effects, it is clear that PCA animals in general have a lower dietary intake and the animals in this series were no exception. The rate of increase in body weight was, however, comparable with that of controls and similar to that described for all other series. Pair feeding was not an effective procedure in a long term experiment involving wire-bottomed cages, because substantial quantities of food were noted in the waste and accurate quantitative recovery was

not carried out. There were no conventional stigmata of dietary deficiency on clinical or microscopical examination and the incidence of intercurrent disease was at the same rate in experimental and control rats, occurring for the most part in old animals.

We thank the Medical Research Council for a project grant awarded to K.W. and Miss Yvonne Maddison for technical help.

Induction of oncogenic transformation *in vitro* by ultraviolet light

SKIN fibroblasts derived from patients with the autosomal recessive disease *xeroderma pigmentosum* are defective in excision repair of photodamage induced by short wavelength ultraviolet light¹. In conjunction with the clinical observation that these patients are extremely prone to develop skin cancer², it has been suggested that DNA repair plays a central role in the process of carcinogenesis. Although methodologies are available for investigating the molecular biology of mammalian DNA repair, studies of carcinogenesis induced by UV have been limited largely to the use of the hairless mouse³⁻⁵. In a preliminary report, DiPaolo and Donovan⁶ reported the induction of transformation in primary hamster embryo cell cultures by ultraviolet light. Mondal and Heidelberger⁷ reported inducing malignant transformation in mouse 10T1/2 cells *in vitro* by exposure to ultraviolet light followed by treatment with tetradecanoyl phorbol acetate. We report here that ultraviolet light of 254-nm wavelength alone is sufficient to induce reproducible transformation in this cell line, and we present the dose-response relationship for this phenomenon.

We used the C3H mouse-embryo-derived cell line designated 10T1/2 clone 8 (ref. 8). Stock cultures were carried in large glass bottles in Eagle's basal medium supplemented with 10% heat-inactivated foetal calf serum (Gibco) and antibiotics. Cells were in passages 11-15. Transformation was scored as previously described^{9,10}. Only type III foci were scored as transformants: these foci grow in a multi-layer, criss-crossed fashion over a background monolayer of normal cells, and exhibit a highly polar, fibroblastic morphology. When injected into syngeneic mice, they cause fibrosarcomas^{10,11} while normal cells do not. The transformed foci we have obtained with ultraviolet light do not differ in morphology from those obtained with X-ray⁹ or

Fig. 1 Transformation frequency per surviving cell as a function of UVL dose for the 10T1/2 mouse fibroblast cell line. 100-mm plastic dishes (Falcon) were seeded with 300–400 surviving cells each to allow them to develop approximately 14 doublings before confluence was reached⁹. The medium was removed 20 h after plating and the cells were irradiated by a bank of five GE G8T5 tubes emitting predominantly 254 nm ultraviolet light at a dose rate of $4.5 \text{ erg mm}^{-2} \text{ s}^{-1}$ at the cell surface. After irradiation, cells were overlaid with fresh medium and returned to a 5% CO_2 humidified incubator held at 37°C . The medium was then changed twice weekly until confluence, then weekly until the seventh week, at which time the cells were fixed with Bouin's solution, stained with Trypan blue and scored for transformants. For each data point, 20–60 transformation plates were used while four plates, each seeded with a cell density one-fifth that of the transformation plates, were terminated at the end of the 2nd week to assay for the number of cells surviving each treatment.

chemical carcinogens^{10,12}. No type III transformants were seen in unirradiated control cultures in any of these experiments.

Figure 1 presents the dose-response curve for ultraviolet-induced transformation. The transformation frequency on the ordinate is plotted as transformants per surviving cell. Clearly this transformation frequency rises initially at low doses, but reaches a plateau after an inflection point at about 75 erg mm^{-2} . The existence of a plateau implies that over this higher dose range a constant proportion of the surviving cells (as assayed by the ability to proliferate indefinitely) is transformed. Thus, when the results are expressed as transformants per irradiated cell (Fig. 2, lower curve), the portion of the curve which corresponds to the plateau is parallel to that part of the dose-response curve for survival (Fig. 2, upper curve). In accordance with our assertion that both survival and transformation are cell-mediated processes¹¹, these data are consistent with the hypothesis that beyond a limiting amount of damage, the relative efficiencies of the cellular repair mechanisms which mediate survival and transformation remain constant. Transformation is genetically selected neither for nor against.

The plateau region in Fig. 1 spans a dose range occupied by both components of the biphasic survival curve (Fig. 2, upper curve). The second component has been shown to represent a subpopulation consisting predominantly of cells

in the G_2 phase of the cell cycle¹³. Host-cell reactivation studies of ultraviolet-irradiated herpes-virus¹⁴ have suggested that the superior survival characteristics of this subpopulation, as evidenced by a greater than twofold increase in the D_0 of the survival curve, can at least in part be attributed to additional repair processes that are operational only in these cells. Our data suggest that no selective advantage has been conferred on this subpopulation with respect to transformation, raising the possibility that the additional repair responsible for the second component of the survival curve represents increased activity of existing processes rather than the operation of a new process. For example, the operation of a more or less error-prone repair mechanism does not seem to be involved.

At the low dose region, although there is an initial shoulder on the survival curve, the curve for transformation per irradiated cell (Fig. 2, lower curve) has an initial

Fig. 2 Dose-response curve for survival (●) and transformation frequency (—) per irradiated cell.

positive slope, at least at doses greater than 10 erg mm^{-2} . It is the combination of the two processes of transformation and cell killing that produces the initial rise and the subsequent decline of this curve. These results are thus qualitatively similar to those for X-ray-induced transformation^{9,15} and other experimental evidence for the existence of a most efficient dose for radiation-induced cancer.

We propose that the transformation seen in these experiments results from the operation of the postreplication repair mechanism which is thought to be error prone. Excision of pyrimidine dimers in the 10T1/2 cell line has been shown to be below the level of detection (personal communication from J. S. Bertram). Moreover, since the cells in our experiments were actively traversing the cell cycle at the time of exposure to ultraviolet light, one can envisage that the presence of unexcised dimers at the first postirradiation DNA synthesis would necessitate the operation of the postreplication repair mechanism. The operation of this mechanism would introduce errors into the genome, some of which would lead ultimately to the fixation of transformation^{16–19}.

Our results suggest that established cell lines such as the 10T1/2 mouse fibroblast might be used to study quantitatively ultraviolet-induced malignant transformation *in vitro*, and in particular to investigate the role of ultraviolet-induced DNA repair processes with respect to the end point of transformation. Such experiments are in progress.

Asbestos cytotoxicity in a long term macrophage-like cell culture

ASBESTOS is well documented as a carcinogen and cocarcinogen in man and experimental animals, and malignancy may appear after exposure to small amounts. In people who have worked with asbestos insulation there has often been a lag of 20 yr between the first exposure and the development of neoplasia. Among these workers a high incidence of carcinoma of the lung and a high frequency of the rare neoplasm mesothelioma has been reported¹. The risk of death from lung cancer is 92 times greater for an asbestos worker who smokes than for someone who is statistically comparable and neither smokes nor works with asbestos. The additive effect of smoking and exposure to asbestos is much greater than that of either factor alone, indicating a cocarcinogenic effect². Exposure to asbestos is not confined to the occupational environment, for asbestos is present in the air of 49 cities in the USA, in some talcum powders and gypsum spackles and in about 400 industrial products³. As the initial *in vivo* response to asbestos involves uptake by host macrophages⁴, we have quantified the effects of standard Union Internationale contre le Cancer (UICC) reference samples of amosite and chrysotile B asbestos *in vitro* on the P388D1 line of malignant cells. These cells have macrophage-like characteristics⁵, but, unlike fresh culture systems, they are capable of reproduction and make long term experimentation possible. We found that asbestos toxicity could be measured as a function of the percentage of cells associated with fibres. Chrysotile was more toxic per unit weight than amosite because it had more fibres per unit weight that could become associated with cells.

Available information on the basic biological effects of asbestos in macrophage cell culture systems has been

reviewed recently⁶. In previous studies fresh peritoneal cultures of hamster, mouse and guinea pig macrophages were exposed to samples of amosite and chrysotile⁷⁻¹². The resulting cytotoxicity was thought to be due to the interaction of asbestos fibres with plasma membrane, and was lessened by increasing the amount of serum. A delayed cytotoxicity was demonstrated by the release of increased amounts of acid phosphatase and β -glucuronidase into the media. In all these cases chrysotile was more toxic per unit weight than amosite.

The crystalline properties of asbestos enabled us to use rectified polarisation optics to detect small birefringent particles of asbestos fibres associated with cells in culture. We used UICC standard reference samples of amosite and chrysotile B, which have been characterised extensively¹³⁻¹⁵. The external surface area of the amosite is $3.3 \text{ m}^2 \text{ g}^{-1}$ while that of the chrysotile is $4.9 \text{ m}^2 \text{ g}^{-1}$. In the optical microscope fibres of amosite and chrysotile vary from 2 to $60 \mu\text{m}$ long. Chrysotile has 6% more fibres $>4 \mu\text{m}$ than amosite. Previous studies have shown that mouse peritoneal macrophages will phagocytose completely asbestos fibres less than $5 \mu\text{m}$ long. Fibres between 5 and $20 \mu\text{m}$ long are sometimes ingested completely while beyond this length complete phagocytosis is not possible.

With both amosite and chrysotile asbestos we found dose-response cytotoxicity. All cultures which reached a nadir of

Fig. 1 Growth curves showing the number of P388D1 cells after exposure to amosite (a) and chrysotile (b). Four 250-ml Falcon tissue culture flasks were each inoculated with 10 ml of 4×10^5 viable P388D1 cells per ml of passage number 37 for the amosite and passage number 41 for the chrysotile. Fischer's media for leukaemic cells of mice plus 10% foetal calf serum with a total volume of 10 ml per flask was used. The flasks were incubated stationary at 37°C in 5% CO_2 in air. After 24 h the medium was changed in all flasks and steam-sterilised asbestos was added to three of the flasks in concentrations of 10, 50 and $100 \mu\text{g ml}^{-1}$ with a total volume of 10 ml per flask. The fourth flask was used as a normal uninoculated control. Medium containing asbestos was left in contact with the cells for 48 h and then removed. Throughout the experiment medium without asbestos was used for complete changes of medium on a regular basis, generally every 2 d. To standardise observations of the culture fields, paper tape with 1-mm holes was taped randomly to the outside of the flasks. There were 10 observation holes for each flask of cells. Using an inverted Nikon microscope fitted with bright field phase objectives and $\times 10$ eyepieces, each field was first focused and observed with a $\times 10$ objective to maintain uniformity of field position, and photographs were then taken through the $\times 20$ objective. This allowed repeated photographs of the same field of cells. Observations and photographs were made immediately before (time zero) the addition of asbestos-containing medium, and then after 8, 24, 48 and 72 h. Each of the 10 fields on each flask was photographed at each time point, and the total of morphologically identifiable cells per photograph was counted in a standardised manner by one observer. Growth curves were derived from these counts. ▲, normal; △, asbestos ($10 \mu\text{g ml}^{-1}$); ●, $50 \mu\text{g ml}^{-1}$; ○, $100 \mu\text{g ml}^{-1}$. At all doses the standard error of the mean (s.e.m.) was less than 15%, except for chrysotile at $50 \mu\text{g ml}^{-1}$ and $100 \mu\text{g ml}^{-1}$ at 48 and 72 h, when it was 33%.

Fig. 2 Morphology of the P388D1 cells after 8–10 d exposure to UICC samples of amosite and chrysotile B asbestos ($50 \mu\text{g ml}^{-1}$). *a*, Normal control after 10 d. Note the large number of small round cells. *b*, After 10 d of exposure to chrysotile ($50 \mu\text{g ml}^{-1}$). Cells are scarce and have changed in size, accompanied by the 'sunburst' morphology. *c*, After 8 d of exposure to chrysotile ($50 \mu\text{g ml}^{-1}$). Note the later conformation of this cell to the shape of the cell-associated fibre. *d*, After 10 d of exposure to amosite ($50 \mu\text{g ml}^{-1}$). The number of cells present and their size morphology should be compared with those of the chrysotile (Fig. 2). ($\times 200$).

growth 72 h after exposure to asbestos maintained the ability to become confluent again within a time proportional to the initial decrease in cell number. Morphological changes occurred after the initial exposure to asbestos. With amosite these included increasing size, numerous thin dendritic projections and an initial change of configuration of a cell conforming to the shape and size of the particles with which the cell was associated. In contrast, although cells exposed to chrysotile did not appear to change shape initially to conform with that of the particles, they often did so later. They soon became larger than normal cells or those exposed to amosite, and took on a characteristic surface appearance with numerous short projections in a "sunburst" pattern.

Table 1 Effects of percentage of cell-associated fibres after 3 h on 72-h cell growth

Asbestos	Dilution ($\mu\text{g ml}^{-1}$)	Time (h)	% of cell-associated fibre (coverslips)	% of cell death at 72 h (bottles)
Amosite	10	3	36.9	4.7
Amosite	50	3	100	38.6
Amosite	100	3	100*	54.0
Chrysotile	10	3	96.4	55.0
Chrysotile	50	3	100†	94.3
Chrysotile	100	3	—‡	99.1

*More than one fibre per cell.

†Three or four fibres per cell.

‡A few cells left.

Untreated P388D1 cells had little birefringence except that of the mitotic spindle. Toxicity of both amosite and chrysotile was related to the percentage of cells with associated birefringent asbestos fibres (Table 1). For example, the similar percentage of cell-associated fibres present after 3 h with amosite at $50 \mu\text{g ml}^{-1}$ and chrysotile at $10 \mu\text{g ml}^{-1}$ correlated with similar percentages of cell death at 72 h. Asbestos fibres in the cultures were counted from photographs taken after 8 h of exposure: there were 378 fibres with the chrysotile, and 366 fibres with the amosite (concentrations as above). Therefore the difference in toxicity per unit weight of chrysotile and amosite relates to the number of fibres associated per P388D1 cell.

Fig. 3 Birefringence of P388D1 cells after 8 h of exposure to chrysotile ($100 \mu\text{g ml}^{-1}$). Coverslips (25 mm in diameter) in 2 ml of medium were inoculated with the same cells and the same concentrations of both types of asbestos. Observations and photographs were made with a Leitz polarisation microscope fitted with Nikon rectified objectives. Under a polarisation microscope the crystalline nature of asbestos produced increased contrast of black or white fibres against a grey background. The cell-associated fibres changed contrast at different compensator settings, indicating that the fibres were birefringent. A and P indicate vibration planes of analyser and polariser, respectively. This photograph was taken at a compensator setting 7° to the side of the background compensation position. Measurements were made of the percentage of cells with associated birefringent asbestos fibres at 3 and 12 h after addition of asbestos.

In our quantitative investigation of cytotoxicity we found asbestos to be as cytotoxic for malignant P388D1 cells as it has been reported to be for non-malignant fresh macrophage culture systems. Therefore these malignant cells would make a good model system for the study of long term effects of asbestos-cell interactions. This *in vitro* system should make it possible to gain some insight into the long *in vivo* macrophage effect in the interim between asbestos exposure and the development of neoplasia.

We thank Miss Jo Abbott for assistance in the preparation of the figures.

Effect of a phorbol ester on a transformation-sensitive surface protein of chick fibroblasts

PMA (phorbol myristate acetate) is the most active of a class of compounds present in croton oil which act as tumour promoters¹⁻³. While PMA possesses little carcinogenicity in its own right, its repeated application to mouse skin causes tumour induction in animals treated up to several months previously with a single subthreshold dose of a carcinogen. If the order of treatments is reversed, that is, if PMA treatment precedes that with the carcinogen, then no tumours are induced. Studies both with mouse skin and with cells in tissue culture indicate substantial effects of PMA on cell behaviour and biochemistry. Many of these effects such as alteration of phospholipid synthesis⁴ or stimulation of Na⁺, K⁺-ATPase and 5'-nucleotidase⁵ relate to the cell membrane. We report here that PMA alters the cell surface protein composition of chick embryo fibroblasts, causing a decrease in the major surface protein LETS (molecular weight 250,000). Previous work by several laboratories has indicated that LETS, which is present on the surface of fibroblasts from a variety of species, either decreases or disappears upon transformation⁶⁻¹¹. Although LETS is highly sensitive to cleavage by proteases such as plasmin¹², its mechanism of loss following transformation remains to be clarified.

We find that the addition of PMA to exponentially growing cultures of secondary chick embryo fibroblasts led to alterations in the pattern of iodinated surface proteins fractionated on sodium dodecyl sulphate (SDS)-polyacrylamide gels. Several bands were decreased in amount,

while at least one new band appeared. Most striking was a reduction in the amount of LETS. After incubation of exponentially growing chick embryo fibroblasts in the presence of PMA for 3 d, the amount of radioactivity in LETS per cell was decreased to 12% of the control value (Fig. 1). The magnitude of the decrease in LETS depends on the basis used for comparison. PMA had little effect under the usual experimental conditions on cell number per plate,

Fig. 1 Effect of PMA on LETS. Secondary chick embryo fibroblasts were plated at 1×10^5 per 60 mm dish in MEM containing 10% tryptose phosphate broth, 5% heat-inactivated chicken serum, penicillin (75 u ml^{-1}) and streptomycin (50 µg ml^{-1}). PMA (Consolidated Midland) dissolved in DMSO was added to each plate to give the indicated final concentrations. The concentration of DMSO in all plates was constant, 0.10%. After 3 d, the cells were iodinated, the proteins fractionated by SDS-polyacrylamide gel electrophoresis on 5% gels, and the amounts of LETS determined as described¹³. The "fraction LETS remaining" gives the c.p.m. in LETS from the plate with PMA per c.p.m. in LETS from the control plate with DMSO. The data were normalised where indicated as follows: (○) Fraction remaining, normalised to cell number; (●) Fraction remaining, normalised to the total surface label migrating on the SDS-polyacrylamide gels with mobility between that of LETS and the marker dye; (△) Fraction remaining, normalised to total protein. All points are the average of duplicate measurements. 1.0 = 31,000 c.p.m. in LETS/gel sample.

total iodine label incorporated, or incorporated iodine label migrating on SDS-polyacrylamide gels with a mobility between that of LETS and of the marker dye bromophenol blue. The decrease in the amount of LETS relative to that of controls was thus similar when normalised to any of these bases. While the amount of LETS relative to other surface label is probably the most relevant value, the volume of chick embryo fibroblasts treated with PMA decreased by a factor of two (manuscript in preparation) and the amount of protein per cell decreased comparably. Consequently, the amount of LETS was reduced to 25% of that in the untreated control when expressed per μg of cell protein.

The growth state of cells in culture is often a significant variable affecting cell surface properties. The observed decrease in LETS caused by PMA probably cannot be explained by such an effect. In the conditions of Fig. 1, the addition of PMA had little effect ($\pm 20\%$) on absolute cell number per plate, on the rate of increase in cell number, and on incorporation of ³H-thymidine per cell.

The amount of PMA required for the half-maximal effect on LETS was $1-2 \text{ ng ml}^{-1}$. This value corresponds to a concentration of $1.5-3 \times 10^{-8} \text{ M}$. Increase in the concentration of PMA between 10 and 100 ng ml^{-1} had no further effect on LETS.

The decrease in LETS following addition of PMA proceeded over a 3-d time course. If cells were replated at this time into fresh PMA-containing medium, this low level was maintained. This loss was slower than that reported after transformation of chick embryo fibroblasts by Rous sarcoma virus⁴. Likewise, full expression of the effects of

PMA on LETS took much longer than its effects on some other properties, for example stimulation of ^3H -deoxyglucose uptake in chick embryo fibroblasts (4 h) or stimulation of cyclic GMP in 3T3 cells (1 min)¹³. It should be noted that the kinetics of loss of LETS after addition of PMA refer to the total amount of LETS remaining on the cell surface. The rapidity of the response to addition of PMA in the production and/or attachment of new LETS remains to be established.

The loss of LETS brought about by PMA was not an irreversible process. Cells treated with PMA regained LETS within 3 d of trypsinisation and replating in medium lacking PMA. PMA was thus not inducing permanent transformation of the cells. The 3-d time course for reappearance of LETS represents an upper limit on the recovery time. Since PMA is highly lipid soluble¹⁴, the possible role of residual cell-bound PMA in delaying recovery of LETS is not known. For comparison, upon shift to the non-permissive temperature of chick embryo fibroblasts transformed by a temperature sensitive mutant of Rous sarcoma virus, LETS returned to normal levels with a 1-d time course⁸.

Fig. 2 Time course of decrease in LETS after addition of PMA. Cells were plated and treated with PMA as described in the legend to Fig. 1, except that the initial plating densities were varied so that the cell densities at the time of iodination were similar. At the indicated times, plates treated with DMSO or PMA were iodinated and LETS determined. Fraction LETS remaining has been normalised to the total surface label migrating on the SDS-polyacrylamide gel with a mobility between that of LETS and the marker dye. (●) PMA, 3 ng ml⁻¹. (■) PMA, 10 ng ml⁻¹.

The direct cause for the decrease in LETS upon treatment of the chick embryo fibroblasts with PMA is not known. For the loss of LETS induced by viral transformation, the following possibilities have been considered: (1) failure of the cells to synthesise LETS, (2) failure of LETS to be properly inserted and bound to the membrane, or (3) proteolytic cleavage of LETS from the membrane after binding. With regard to an earlier level of regulation, the possibility that PMA does not affect LETS *per se* but regulates some intermediate property, which itself determines the level of LETS, deserves consideration. In either case, the understanding of the mode of action of PMA on LETS is of particular interest in that it provides a new approach and may potentially provide new insight into the control of this same surface component by Rous sarcoma virus.

A number of the effects of PMA on cells resemble those induced by transformation. These effects include (1) decrease in LETS, (2) increase in plasminogen activator¹⁵, (3) release from contact inhibition¹⁶, (4) increase in cyclic GMP¹³ and decrease in cyclic AMP concentrations¹⁷, and (5) reduction in cell adhesion, loss of orientation on the

plate and alteration in morphology¹⁸. Caution must be exercised in extrapolating these results since a number of these changes have been observed in systems other than those, for example the mouse epidermis and certain cell culture systems¹⁹, where the promoting effects of PMA have been characterised. Nonetheless, the parallels between the effects on cells of PMA and of transformation are consistent with the hypothesis that tumour promoters might function by causing the conversion of cells from a normal phenotype to one more resembling the transformed state, thus facilitating expression of the genotype of latent tumour cells.

Kinetics of lymphocyte stimulation by concanavalin A

AN important problem pertinent to the mechanism of lymphocyte stimulation with a nonspecific mitogen is how long lymphocytes must be exposed to the mitogen to attain maximal stimulation. In the case of the stimulation of human and murine lymphocytes by concanavalin A (con A), the cells are irreversibly committed to stimulation if the lectin is present on the cell membranes for some 18-20 h after the start of the culture¹⁻³. Here we report studies on the kinetics of the stimulation of mouse splenic lymphocytes by con A. Our data indicate that two pulses of con A (0-3 h and 15-18 h after the start of the culture) can stimulate the cells to the same degree as the continuous exposure of the cells to con A for 18 h, suggesting that two signals are necessary for the con A stimulation of lymphocytes. We also show that the first signal is possibly given by the influx of Ca²⁺.

As shown in Fig. 1, when con A on the membranes of mouse splenic lymphocytes was removed by washing with methyl α -D-mannopyranoside (α -MM) at various times after the start of the culture, the response of the cells as measured by ^3H -thymidine incorporation did not increase linearly with the time of the exposure to con A, but it increased rapidly when the cells were exposed to con A for periods longer

Fig. 1 The effect of con A removal at different times after the start of the culture on the ³H-thymidine incorporation by con A-stimulated mouse splenic lymphocytes. Splenic lymphocytes (2×10^6 cells ml^{-1}) purified from C3H/He mice by Ficoll-Urografin density gradient centrifugation⁶ were incubated in a silicone-coated test tube (1×10 cm) with con A ($4 \mu\text{g ml}^{-1}$) in 1.0 ml of RPMI 1640 medium supplemented with 10% foetal calf serum, 2 mM glutamine and kanamycin ($60 \mu\text{g ml}^{-1}$) at 37°C in a humidified atmosphere of 5% CO_2 and 95% air. At different times, cultures were washed in the culture medium and resuspended in 1.0 ml of 0.05 M α -MM in the culture medium. After 10 min, the cells were collected by centrifugation (300g, 5 min) and resuspended in 1.0 ml of the culture medium. Incorporation of ³H-thymidine ($1.0 \mu\text{Ci}$ per culture; specific activity 23 Ci mmol^{-1}) between 28 and 42 h after the start of the culture was measured by the method described previously⁶. Each point represents the average of three cultures and vertical bars represent ± 1 s.e.m. As control experiments, the incorporation of ³H-thymidine of an unstimulated culture not treated with α -MM (\square) and of a culture continuously exposed to con A for 42 h (\blacksquare) was shown.

than 12 h. No inhibition was observed when con A was removed at times later than some 18–20 h after the initial binding of the lectin.

We then compared the response after various pulsed exposures to con A with that after the continuous exposure to the lectin for 18 h. Within experimental error, two successive 3-h exposures (0–3 and 15–18 h) separated by an

interval of 12 h yielded the same level of response as continuous exposure for 18 h (Table 1), whereas, when the cells were pulsed with con A only for 3–6 h at the beginning of the culture, or for 3 h between 15 and 18 h, the response was only 25–40% of that seen with an 18-h exposure to con A. These observations were further confirmed by the comparison of the kinetics of DNA synthesis among the cultures which were pulsed with con A at various times. The culture pulsed twice (0–3 and 15–18 h) with con A gave a similar DNA synthesis profile to that of the culture in which the cells were in contact with con A continuously for 18 h (Fig. 2), reaching maximal incorporation of ³H-thymidine by 40 h after the initial binding of con A to the cell membranes. In the other experiments, we shortened the length of the two-pulsed exposure to con A to 1 or 2 h each, but the response was found to be 70–80% of that seen with two 3-h exposures. The requirement of the presence of mitogen on the cell surface at two different stages—at the beginning of culture and at the period just before the onset of DNA synthesis—for maximal lymphocyte stimulation has also been suggested by Weber *et al.*⁴

Since recent investigations have shown that the enhanced uptake of Ca^{2+} is one of the common events which occur within minutes of the binding of mitogen to lymphocytes^{7,8}, we replaced the first exposure to con A (0–3 h) with treatment with calcium ionophore A23187 which has also been shown to be mitogenic to lymphocytes^{9–11}. The data in Table 1 reveal that the pulsed treatment of lymphocytes with A23187 for 3 h at the beginning of the culture followed by a 3-h exposure to con A between 15 and 18 h after the start of the culture is equally effective in the activation of lymphocytes as the two pulses of con A (0–3 and 15–18 h). The addition of EGTA (5×10^{-4} M) to the culture medium with A23187 at the beginning of the culture, however, reduced the stimulation to 60–70%. Furthermore, the response of the culture pulsed with con A first (0–3 h) and then with A23187 (15–18 h) was much smaller than that of the culture pulsed with A23187 first and with con A later.

These results suggest that the Ca^{2+} influx into the cell mediated by ionophore or induced by the mitogenic lectin on the cell membranes possibly plays an important part in the triggering of lymphocyte stimulation as the first signal. In view of the recent findings that guanylate cyclase activity of lymphocytes is dependent on the intracellular

Mouse splenic lymphocytes were cultured with con A ($4 \mu\text{g ml}^{-1}$) or with A23187 ($0.05 \mu\text{g ml}^{-1}$) as described in the legend of Fig. 1. For the removal of con A and A23187, the following washing procedure was carried out in both cases. At an appropriate time after the start of the culture, cells were washed once in the culture medium and resuspended in 1.0 ml of 0.05 M α -MM in the culture medium. After 10 min, the cells were collected by centrifugation (300g, 5 min) and resuspended in 1.0 ml of the culture medium. Incorporation of ³H-thymidine between 39 and 42 h after the start of the culture was measured by the method previously described⁶. Each value represents the mean \pm s.e.m. of three cultures. The horizontal bars represent the time during which con A (C) or A23187 (A) was present.

Fig. 2 The effect of length of exposure to con A on the kinetics of DNA synthesis in mouse splenic lymphocyte cultures. Culture of lymphocytes and the removal of con A from each culture were performed as described in the legend of Fig. 1. ○, Control cultures without con A. Periods for which the cultures were incubated with con A ($4 \mu\text{g ml}^{-1}$). □, 0–3; ■, 0–6; ●, 15–18; ▲, 0–3+15–18; △, 0–18 h. DNA synthesis was measured with a terminal 3-h pulse of ^3H -thymidine ($2.5 \mu\text{Ci}$ per culture). Each point represents the average of three cultures.

level of calcium ion¹² and microtubule function is controlled by the local concentration of Ca^{2+} in the cell cytoplasm^{13,14}, the mitogen-induced influx of Ca^{2+} into lymphocytes triggers the stimulation of the cells possibly by the elevation of cyclic GMP level in the cells and/or the functional alteration of microtubular assembly which modulates the topography of cell-surface receptors. After approximately 12–15 h from the influx of the first signal, the cells attain a preactivated state, and these then proceed to the DNA synthetic period (S phase) if the second signal is provided by the presence of mitogen on the cell membrane. It may, however, be necessary to estimate actual numbers of responding cells during the course of the exposure to con A to validate this assumption further. Investigation of the nature of the second signal and its mechanism of action should enable us to elucidate the triggering mechanism of lymphocyte activation.

Rat platelets aggregate in the absence of endogenous precursors of prostaglandin endoperoxides

THE prostaglandin (PG) endoperoxides, PGG_2 and PGH_2 , are thought to have a function in human platelet aggregation, since they are formed during thrombin-induced aggregation¹. They induce aggregation on addition to platelet-rich plasma (PRP), either directly or after conversion to thromboxane A_2 (TXA_2)². TXA_2 (half life ~ 30 s) is formed *in vitro* by a microsomal enzyme which is insensitive to inhibition by aspirin-like drugs^{3,4}. It is therefore distinct from the cyclo-oxygenase that converts arachidonic acid (AA) into PG endoperoxides. AA, after incorporation into membrane phospholipids, is liberated during thrombin-induced aggregation and is then almost completely metabolised⁵ by the cyclo-oxygenase and AA-lipoxygenase⁶. Therefore, we tested platelets of animals that were deprived of AA, and still observed aggregation with collagen, indicating that PG endoperoxides and TXA_2 are not essential for aggregation.

Feeding mammals with an essential fatty acid-deficient (EFAD) diet, lacking linoleic acid ($18:2$, $n-6$), results in a decrease of *bis*-homo- γ -linolenic acid ($20:3$, $n-6$) and AA ($20:4$, $n-6$), both PG precursors. The part played by AA in membrane phospholipids is replaced by eicosatrienoic acid ($20:3$, $n-9$), which is not a substrate⁷ but a competitive inhibitor⁸ of the cyclo-oxygenase. Pregnant rats (Wistar, TNO, Zeist, The Netherlands) were placed on a diet containing 4% hydrogenated cocofat (Hope Farms), 5 d before the expected day of delivery⁹. After weaning, the newborn rats were kept on EFAD food; controls received 3.5% of their calories as linoleic acid. Apart from reduced growth¹⁰, the EFAD condition of the rats was clearly demonstrated by fatty acid analysis of erythrocytes (Table 1). A marked reduction of the linoleic acid family ($18:2$, $n-6$; $20:3$, $n-6$; $20:4$, $n-6$) was observed in favour of the oleic acid ($18:1$, $n-9$) family. The criterion of Holman¹⁰ for EFA deficiency—a ratio between eicosatrienoic acid ($20:3$, $n-9$) and AA ($20:4$, $n-6$) greater than 0.4—was amply exceeded.

Fig. 1 Differences in bioassay of rat platelet RCS and PGH_2 . The cascade, with rabbit aorta, rat stomach and rabbit coeliac artery strips, was superfused with a Krebs' solution (2.5 ml min^{-1} , 37°C) containing a mixture¹¹ of antagonists to inactivate serotonin, histamine, acetylcholine and catecholamines and indomethacin ($3 \mu\text{M}$) to prevent PG synthesis by the tissues. Cumulative¹² doses of PGE_2 and PGH_2 in glucose-free Krebs' were superfused over the tissues. Samples (0.1 ml) of normal PRP, preincubated for 3 min at 37°C with different concentrations of NaN_3 , were superfused directly (▲) on the cascade, 1 min after addition of collagen ($40 \mu\text{g ml}^{-1}$). Preparation of PRP and aggregation was performed as described in Table 2.

Table 1 Fatty acid composition of total fat from normal and EFAD rat erythrocytes

Fatty acid	Normal % weight	EFAD % weight
16:0	29.8±1.3	28.9±0.9
18:0	20.0±1.5	17.5±2.1
18:1, <i>n</i> -9	10.2±1.1	19.8±0.7
18:2, <i>n</i> -6	7.6±0.7	0.8±0.04
20:3, <i>n</i> -6	0.2±0.04	<0.1
20:3, <i>n</i> -9	<0.1	8.7±0.9
20:4, <i>n</i> -6	18.6±1.7	4.5±0.6
<i>R</i> =20:3, <i>n</i> -9 20:4, <i>n</i> -6	<0.013±0.002	1.97±0.09

Heparinised blood was obtained by cardiac puncture from male rats (23–25 weeks old) under ether anaesthesia. After centrifugation (30 min, 950g) plasma and 'buffy coat' were removed and the erythrocytes were washed three times with 6 volumes of 10 mM EDTA in saline. Total fat of 5 ml packed cells was isolated²⁴ by two extractions with 19 volumes of chloroform-methanol (2:1). After saponification of 5 mg lipid, the fatty acids were extracted (pH=4) with pentane (3×25 ml), dried over anhydrous Na₂SO₄ and methyl esters were prepared in a fresh ethereal diazomethane solution (nitrogen atmosphere). The fatty acid pattern was determined with a Hewlett Packard 5750 gas chromatograph, equipped with a 4 foot×3-mm column (3% EGSS-X on gaschrom Q; Chrompack, The Netherlands) and a flame-ionisation detector. The equivalent chain length values were compared with those of a mixture of standard fatty acids and with the data of Hofstetter²⁵. Weight percentages were determined by triangulation, and expressed as means (±s.e.) of four rats.

Aggregation induced by different stimuli was investigated in both normal and EFAD PRP (Table 2) and no significant differences in platelet number were observed *in vivo*¹¹ or in PRP. In rat platelets adenosine diphosphate (ADP) induces only primary aggregation¹³, which is probably independent of the PG-endoperoxide mechanisms¹³. Therefore, a supra-maximal dose of ADP (40 μM) was added after each aggregation, serving as control for the aggregatory capacity of each sample. ADP induced equal aggregation in normal and EFAD PRP, except at the lowest dose, when EFAD PRP aggregated less (56%) than normal PRP. Although electron microscopy did not reveal membrane differences, this result might reflect an altered membrane structure¹⁴.

The sensitivity of rat PRP towards the PG-endoperoxide PGH₂ seemed to be low. At low doses (from 500 ng ml⁻¹) PGH₂ only induced a minor shape change as seen from a small decrease in light transmission and diminished oscillations. With 1 μg ml⁻¹ a small transient aggregation was observed. Only small amounts of PGH₂ may enter the rat cells and therefore may not be converted to TXA₂ by the internal microsomal enzyme system. Preloading of PRP with a high concentration of linoleic acid, in order to eliminate binding of PGH₂ to albumin¹⁵, did not alter rat PRP responses. No significant differences were observed between EFAD and normal PRP (*P* > 0.05, analysis of variance) in any condition.

EFA deficiency did not alter the aggregating efficacy of high collagen doses, but inhibited almost completely aggregation by a dose giving half maximal responses in normal PRP. Since feedback inhibition by PGD₂, the most potent inhibitor of human platelet aggregation^{16,17}, is absent in rat platelets¹⁷, the diminished response from platelets with a low internal AA content might be caused by a rate-limiting production of PG-endoperoxides and TXA₂. To check this assumption the release of substances derived from AA and involved in aggregation was assessed directly on a cascade¹⁸ of isolated tissues¹⁹.

The substances formed by aggregating normal rat PRP, were differentiated by using a combination of rabbit aorta^{19,21}, rat stomach^{18,19} and rabbit coeliac artery²⁰ strips, in the presence of appropriate antagonists²¹ (Fig. 1). PRP, 1 min after addition of collagen (40 μg ml⁻¹) contracted all tissues. All smooth muscle-stimulating activities, including rabbit aorta contracting substance¹⁹ (RCS) were lipid soluble, because they were removed after passage through a small Amberlite XAD-2

column, as shown previously²¹. Rabbit coeliac artery has been reported to contract to TXA₂ and to show relaxation towards PGE₂ and PGH₂ (ref. 20). The latter observation was not confirmed and small contractions were observed with higher doses of PGH₂. TXA₂ may be generated by aggregating PRP since rabbit coeliac artery shows great sensitivity towards the contractile activity of TXA₂ (ref. 20).

Rabbit aorta is sensitive towards PGH₂, but TXA₂ is far more potent than the PG-endoperoxides^{3,4,20}. Although comparison of sets of rabbit aorta and coeliac artery responses towards control PRP (0 μM NaN₃) indicates that a TXA₂-PG-endoperoxide balance seems to exist, the main component of RCS is probably TXA₂. This was confirmed by the half life of RCS at 37 °C, 32±6 s (*n* = 5), following removal of platelets by quick filtration through a Millipore filter to avoid new TXA₂ formation. The half life of PGH₂, stirred in platelet-poor plasma (900 r.p.m., 37 °C), was 125±42 s (*n* = 8). These half lives were estimated from linear plots of the logarithms of rabbit aorta contractions at different times. Finally, inhibition of RCS by low doses of NaN₃, without altering the rat stomach contractions, again indicated that RCS differs from PG-endoperoxides. Rat stomach is stimulated by PGE₂, to a lesser extent by PG-endoperoxides²¹ and PGD₂, but hardly at all by TXA₂ (refs 3, 4, 20). The mechanism of azide interference with TXA₂, also demonstrated²² in rabbit PRP aggregated by AA, remains obscure. Possible explanations are inactivation of the TXA₂-forming microsomal system or an enhanced conversion of TXA₂ to the N₃ analogue of the inactive TXB₂ (ref. 2). As expected, no differences were observed in IC₅₀ values for TXA₂ and PGE inhibition by the cyclo-oxygenase inhibitors indomethacin and eicosatetraynoic acid, because both act at a stage before TXA₂ formation (unpublished results).

Fig. 2 Time courses of aggregation and generation of RCS (mainly TXA₂), PG endoperoxides and PGE by aggregating normal (●) and EFAD (○) PRP. Samples (0.1 ml) of rat PRP, aggregating after addition of 40 μg ml⁻¹ collagen (arrow) were superfused directly on rabbit aorta, and rat stomach strips (see legend Fig. 1). The upper part shows the changes in light transmission during aggregation of normal PRP together with release of RCS (expressed in units, 1 unit = 1 ng PGH₂ ml⁻¹). The lower part shows rat stomach contractions, calibrated with PGE₂. Each value is the mean (±s.e.) of four experiments, unless indicated otherwise.

Table 2 Comparison between the aggregatory capacity of normal and EFAD platelet-rich plasma (PRP)

	Normal PRP	EFAD PRP
Platelet count 10 ⁸ cells µl ⁻¹	618±38 (5)	729±31 (5)
Aggregation inducer	% Aggregation	% Aggregation
ADP 2.50 µM	95.7±2.6 (5)	90.8±1.5 (5)
0.80 µM	76.9±5.4 (5)	75.7±3.9 (5)
0.25 µM	25.9±3.0 (5)	14.5±2.4 (5)*
PGH ₂ 1 µg ml ⁻¹	25.0±5.5 (4)	17.9±4.0 (3)
Linoleic acid (10 mM)+ PGH ₂ 1 µg ml ⁻¹	14.7±4.3 (3)	15.5±2.7 (3)
Collagen 40 µg ml ⁻¹	95.2±1.6 (5)	95.3±1.6 (5)
4 µg ml ⁻¹	53.6±10.3 (5)	3.1±1.5 (5)†

PRP was collected after centrifugation (15 min, 200g, room temperature) of heparinised blood (see Table 1) and diluted with platelet-poor plasma (30 min, 950g) to A 602 nm/1 cm=0.9. PRP was prepared daily, avoiding any glass contact and stored at 0 °C. The platelet number was determined with a Coulter counter (Model A). PRP (200 µl) was preincubated (3 min, 900 r.p.m., 37 °C) with 25 µl Tyrode (glucose and Ca²⁺-free) or with 25 µl Tyrode containing linoleic acid. Aggregation was started by addition of 25 µl inducer and maximal increase in light transmission was measured (Payton Single Channel Module, Payton Ass. Inc., Buffalo, New York). Results are expressed as percentages of maximal increase with 40 µM ADP, added in 10 µl 5 min after starting aggregation. Collagen (Bovine achilles tendon, Sigma, final concentration 400 µg ml⁻¹) was suspended in 18 mM acetic acid. PGH₂ was stored at -70 °C in diethylether and after evaporation, it was immediately dissolved in Tyrode and tested. ADP (Boehringer) and linoleic acid (Merck) were also dissolved in Tyrode. The values are the means (± s.e.) of the indicated number of experiments.

* $P < 0.05$, † $P < 0.01$, Wilcoxon test, two-sided.

Release of TXA₂, PG-endoperoxides and PGE by normal and EFAD PRP, together with an aggregation pattern of normal PRP, is shown in Fig. 2. Although RCS is mainly TXA₂, the rabbit aorta strips were calibrated with PGH₂. No activity was detectable during preincubation. At 20 s after collagen addition, when aggregation is starting after a lag period, TXA₂ was almost maximally generated by normal PRP. TXA₂ concentration was practically unaltered at 30 s, when light transmission increased steeply. At 1 min, however, when aggregation is completed for 75%, TXA₂ is already disappearing and when maximal increase in light transmission, together with oscillations due to aggregates, was observed (3 min), hardly any TXA₂ was detectable. EFAD PRP generated only 16% of the TXA₂ released by normal PRP 1 min after collagen, but aggregation of EFAD PRP was unaltered with this high collagen dose (also shown in Table 2). PGE formation showed the same pattern, with the exception that a residual activity was observed which was stable for up to 2 h after aggregation. This activity behaved like PGE after extraction, column chromatography and differential bioassay on rat stomach strip and rat colon (H. B. and I. L. B., in preparation). Since TXA₂ is not spasmogenic on rat stomach³, the initial peak of activity was probably composed mainly of PG-endoperoxides. These compounds degrade to PGE₂ (ref. 23) and other catabolites. Again EFAD PRP generated less PGE (20% or less when assessed at 7 min or later) and less unstable PG-endoperoxide-like activity (24%, 1 min) than normal PRP. The decreased formation of TXA₂ and PGE by EFAD platelets was not a result of decreased cyclo-oxygenase activity. During AA (0.325 mM) induced aggregation PG-endoperoxide-like activity (1 min) and PGE (7 min) were formed in equal amounts by normal and EFAD PRP.

Although this differential bioassay is less accurate than gas-liquid chromatography-mass spectrometry of degradation products of TXA₂ and PG-endoperoxides, it gives a dynamic picture of the presence of separate biologically active substances during platelet aggregation. These data, obtained with platelets in a more physiological environment than in other studies^{3,5}, indicate that the capacity of platelets to aggregate with threshold

doses of collagen is dependent on the availability of endogenous AA. Decreased generation of TXA₂ and PG-endoperoxides coincides with diminished aggregation by EFAD platelets, although their sensitivity towards PG-endoperoxides and their cyclo-oxygenase activity are unchanged. With high collagen concentrations the PG-endoperoxide generating system is replaced by other mechanisms because a reduction of endogenous AA did not prevent platelet aggregation. Finally, specific inhibition of TXA₂ formation, as shown with sodium azide, might provide opportunities to reduce platelet aggregation without affecting the formation of PGD₂, which has strong anti-thrombotic effects in human platelets.

We thank Drs J. E. Vincent for discussions, A. Montfoort for assistance in fatty acid analysis, J. J. Michiels for preparation of electron micrographs, D. H. Nugteren (Unilever Research, Vlaardingen, The Netherlands) for gifts of PGH₂, and J. E. Pike (Upjohn company, Kalamazoo) for gifts of PGE₁, PGE₂ and PGF_{2α}. Mr F. J. Zijlstra and Miss A. L. Heisterkamp gave technical assistance and Dr M. Parnham read the manuscript. H. B. was supported by the Dutch Foundation for Medical Research, FUNGO.

Stimulation of 'irritant' receptors and afferent C-fibres in the lungs by prostaglandins

The lungs are among the many organs that generate, release and destroy prostaglandins (PGs)¹. It has been suggested that PGs act as 'local hormones'², so that prostaglandins E₁ and E₂, which relax the smooth muscle of bronchi and pulmonary blood vessels in many species, and F_{2α}, which contracts it, may be implicated in normal regulation of airway and pulmonary vascular calibre³. PGF_{2α} has been proposed as a causal factor in asthma⁴. The bronchoconstrictor effect of PGF_{2α} is reduced by atropine, hence a reflex component may be involved⁵. Cough and airway irritation have been reported in clinical trials of PGE₁ and PGE₂ as bronchodilators in the treatment of asthma^{6,7}. Thus PGs may stimulate afferent nerve endings in the lungs, and there has been speculation as to which endings are involved. We have recorded impulse activity from rapidly-adapting pulmonary stretch ('irritant') receptors^{8,9} and afferent C-fibre endings^{10,11} in the lungs of anaesthetised

Fig. 1 Comparison of the effects of $\text{PGF}_{2\alpha}$ and PGE_2 on an 'irritant' receptor (large spikes) and a C-fibre ending (small spikes). Both endings were located in the lower lobe of the left lung. Conduction velocity was 27.2 m s^{-1} in the 'irritant' fibre, and 1.3 m s^{-1} in the C-fibre. *a*, Before, and *b*, 16 s after injection of $\text{PGF}_{2\alpha}$ ($4 \mu\text{g kg}^{-1}$) into the right atrium. Interval of 6 min between *b* and *c*. *c*, Before, and *d*, 42 s after injection of PGE_2 ($20 \mu\text{g kg}^{-1}$) into the right atrium. From above downwards in each record: 1 s time trace; ECG, electrocardiogram; AP, action potentials recorded from an afferent filament of the left vagus nerve; P_T , tracheal pressure (upstroke representing inflation).

dogs. When $\text{PGF}_{2\alpha}$ was injected into the right atrium, lung 'irritant' receptors were strongly stimulated. Injection of PGE_2 , by contrast, caused marked and prolonged stimulation of lung C-fibres.

We recorded impulses from fine strands (containing one, or at most two, active fibres) of the cervical vagus nerve in dogs anaesthetised with Dial-Nembutal. The two types of lung afferent were identified by their patterns of discharge, by their responses to various procedures (for example hyperinflation of the lungs; injection of chemicals known to stimulate them), and by the conduction velocity of their fibres⁸⁻¹¹. The chest was open so that we could determine by direct mechanical stimulation the location of the ending whose impulses we had recorded. The lungs were ventilated at constant tidal volume by a positive pressure pump. Tidal CO_2 was monitored continuously, and maintained within normal limits. We measured systemic and pulmonary arterial blood pressure and tracheal pressure. Drugs were injected into the right and left atrium, or administered as aerosols generated by an ultrasonic nebuliser (DeViblis). Some afferent vagal C-fibre endings in the lung are located in structures supplied by the pulmonary circulation, others are in structures supplied by the bronchial circulation¹¹. However, PGs had similar effects on these two groups of C-fibres, and the results have been combined.

Injection of $\text{PGF}_{2\alpha}$ ($1-8 \mu\text{g kg}^{-1}$) into the right atrium stimulated all 23 'irritant' receptors examined. These doses are within the range used by Wasserman⁵ to produce changes in airway mechanics in anaesthetised dogs. In the majority of experiments reported here we did not examine the dose-response relationship in detail because the recording life of the fine vagal strands was often limited; and we had to determine the precise location of the ending before the fibre became inactive. In most cases, therefore, we used a dose of $4 \mu\text{g kg}^{-1}$ to examine the response of the ending. Latencies of onset ranged from 5 to 25 s (mean 12.2). Activity increased from

1.7 ± 0.4 impulses s^{-1} (mean \pm s.e.) during the control period to 10.4 ± 2.0 impulses s^{-1} , when averaged over one respiratory cycle at the peak of the response. Firing remained above control for 30-120 s (mean 73.5). There was invariably an increase in peak tracheal pressure ($2.1 \pm 0.3 \text{ cm H}_2\text{O}$). The observed cardiovascular effects, consisting of an increase in pulmonary arterial pressure, and usually a small rise in systemic arterial pressure, confirm earlier findings¹². 'Irritant' receptor firing and tracheal pressure also increased when an aqueous solution of $\text{PGF}_{2\alpha}$ ($0.05-0.1 \text{ mg ml}^{-1}$) was administered as an aerosol. A typical response to $\text{PGF}_{2\alpha}$ injected into the right atrium is seen in Fig. 1.

The majority of 'irritant' receptors are believed to be in the larger airways¹³, which are supplied by the bronchial circulation. Nevertheless, injection of $\text{PGF}_{2\alpha}$ ($2-12 \mu\text{g kg}^{-1}$) into the left atrium stimulated only one out of eight receptors tested; tracheal pressure increased on average by only $0.2 \text{ cm H}_2\text{O}$, and arterial pressures were unchanged. Thus $\text{PGF}_{2\alpha}$ stimulates 'irritant' receptors regularly only when it has access to the pulmonary circulation, from which site it produces its maximal bronchoconstrictor effects. This observation, coupled with evidence that PGs are largely destroyed in a single passage through the lung¹, favours the hypothesis that 'irritant' receptor stimulation is not primarily due to the effects of $\text{PGF}_{2\alpha}$ on the nerve ending, but is secondary to changes in lung mechanics. This interpretation was strengthened by our finding that administration of an aerosol of isoproterenol ($0.1-0.2 \text{ mg ml}^{-1}$) significantly reduced the effect of $\text{PGF}_{2\alpha}$ on both receptor activity and tracheal pressure (Table 1). Similarly, when PGE_2 ($10-20 \mu\text{g kg}^{-1}$), which has been shown to reduce the bronchoconstrictor effect of $\text{PGF}_{2\alpha}$ ^{14,15}, was injected into the right atrium 1-6 min before injection of $\text{PGF}_{2\alpha}$, there was a significant reduction in the effect of $\text{PGF}_{2\alpha}$ on both receptor firing and tracheal pressure. However, in experiments in which we used isoproterenol, PGE_2 , or atropine to antagonise the bronchoconstrictor effects of $\text{PGF}_{2\alpha}$, there were a few instances in which 'irritant' receptor stimulation by $\text{PGF}_{2\alpha}$ was unchanged. Hence the possibility that $\text{PGF}_{2\alpha}$ also stimulates 'irritant' receptors directly cannot be ruled out.

If $\text{PGF}_{2\alpha}$ has a causative role in asthma⁴, then our finding that $\text{PGF}_{2\alpha}$ stimulates 'irritant' receptors acquires considerable pathophysiological significance. It has been postulated that stimulation of 'irritant' receptors by histamine causes a reflex bronchoconstriction which is superimposed on the direct action of the drug^{16,17}. The same may be true for $\text{PGF}_{2\alpha}$.

There was a similar but less pronounced stimulation of 14 of 19 lung C-fibres when $\text{PGF}_{2\alpha}$ ($2-12 \mu\text{g kg}^{-1}$) was injected into the right atrium, impulse frequency for the group as a whole

Table 1 Reduction of effects of $\text{PGF}_{2\alpha}$ by isoproterenol aerosol

		'Irritant' receptor activity (impulses s^{-1})	Peak tracheal pressure (cm H_2O)
A	Control	1.4 ± 0.5	10.9 ± 0.5
	$\text{PGF}_{2\alpha}$	12.6 ± 2.1	12.9 ± 0.7
B	Control	2.1 ± 0.6	10.9 ± 0.5
	$\text{PGF}_{2\alpha}$	4.5 ± 0.7	11.2 ± 0.5

Effects on 'irritant' receptor activity and tracheal pressure of injecting $\text{PGF}_{2\alpha}$ ($2-8 \mu\text{g kg}^{-1}$) into the right atrium. Results comprise 13 complete trials on eight receptors. The data in the upper two lines (labelled A) were obtained before administration of isoproterenol; data in the lower two lines (labelled B) were obtained after an aerosol of isoproterenol ($0.1-0.2 \text{ mg ml}^{-1}$ solution) had been administered for 5 min. Mean values are given together with their standard errors. The reduction by isoproterenol of the effects of $\text{PGF}_{2\alpha}$ was highly significant ($P < 0.002$).

increasing from 0.5 ± 0.1 to 2.1 ± 0.5 impulses s^{-1} (Fig. 1). The latency of response was 24 ± 2.5 s, and firing remained above control levels for 123 ± 20.8 s.

Surprisingly, PGs of the E series, which are known to be highly irritant^{6,7}, had only minor effects on 'irritant' receptors, only 6 of 12 receptors being stimulated by PGE_2 ($10\text{--}20 \mu g \text{ kg}^{-1}$) injected into the right atrium. The increase in activity for the group as a whole was only 1.4 ± 0.5 impulses s^{-1} and the effect lasted no more than four to five respiratory cycles. On average, peak tracheal pressure decreased by $0.1 \text{ cm H}_2\text{O}$. PGE_2 ($5\text{--}10 \mu g \text{ kg}^{-1}$ injected into the right atrium), however, was a powerful stimulant of 19 of 21 lung C-fibre endings, impulse activity increasing from 0.6 ± 0.1 to 5.9 ± 0.9 impulses s^{-1} (with a latency of response of 14.7 ± 0.8 s) (Fig. 1). The effect, moreover, was extremely prolonged (average duration 6.5 min); indeed 15 min sometimes elapsed before firing returned to control levels. This was surprising in view of the reported rapid inactivation of PGs¹. The concomitant hypotensive effect also was long-lasting, a finding that agrees with earlier observations on PGE_1 ¹². We have no explanation for these prolonged effects.

In the same dose range, PGE_1 had similar but less pronounced effects on C-fibre endings. The relative potencies of PGE_1 and PGE_2 on C-fibre endings parallel the observation that, in man, the irritant properties of PGE_1 are less than those of PGE_2 (ref. 7). Furthermore, in our experiments, administration of isoproterenol aerosol did not reduce the stimulation of lung C-fibre endings by PGE_2 , and in man isoproterenol does not prevent the cough response to PGE_2 (ref. 6). Hence it is conceivable that C-fibres, rather than 'irritant' receptors, are responsible for PGE -induced cough.

We thank Dr John Pike of the Upjohn Company for the prostaglandins used in these experiments. This work was supported by a grant from the National Heart and Lung Institute.

Multiple sclerosis, Guillain-Barré syndrome and myelin basic protein-specific cellular antibody

MULTIPLE sclerosis (MS) and the Guillain-Barré syndrome (GBS) are demyelinating diseases of unproven aetiology and

pathogenesis, in which infectious and immunological factors have been suggested to have a role^{1–3}. The notion that sensitisation to basic proteins from myelin might be involved has arisen from certain similarities between these human diseases and the autoimmune demyelinating diseases of animals, experimental allergic encephalomyelitis (EAE) and experimental allergic neuritis (EAN)⁴. EAE is caused by sensitisation to the encephalitogenic basic protein from central myelin (CNS-BP) and EAN by sensitisation to peripheral myelin. One of the two basic proteins of peripheral myelin, P2 protein⁵, is considered a likely candidate for the neuritogenic factor⁶. To help determine whether sensitisation to myelin basic proteins is involved in the pathogenesis of MS and GBS, we have used horseradish peroxidase (HRP)-labelled myelin basic proteins^{7,8} to seek evidence of an antibody of this specificity in nervous system plasma cells in these diseases. Our negative findings do not support a pathogenetic role for myelin basic proteins in MS or GBS.

In rabbits with EAE, it has been shown that plasma cells specifically binding a conjugate of CNS-BP and HRP are present in tissue sections of lymph nodes from day 8 until at least day 54 after immunisation^{9,10}. Such cells are also present in early spinal cord lesions¹¹, the only time at which they have been sought. Likewise in rabbits with acute EAN, plasma cells specifically binding an HRP conjugate of P2 protein are present in lymph nodes and dorsal root ganglia (DRG)⁴. The binding of these conjugates by plasma cells in these disorders is believed to reflect the presence of intracellular IgG antibody specific for the respective basic proteins¹⁰. The conjugation procedure diminishes somewhat the immunological reactivity of CNS-BP (refs 11, 12), the method does not detect plasmalemmal staining as might be anticipated to occur on CNS-BP reactive lymphocytes (our unpublished observations), and no relationship has been proved between the reactive plasma cells and the pathogenesis of EAE or EAN. Nevertheless, the presence of these basic protein-binding cells serves as an indicator of the presence of immunological reactivity towards the particular antigen, and their presence in the nervous system lesions puts them in a position of potential pathogenetic importance.

There is no conclusive evidence in MS and GBS that sensitisation to myelin basic proteins is involved in pathogenesis. A relationship was, however, recently reported between acute exacerbations of MS and sensitisation to CNS-BP, as measured by a macrophage migration inhibition assay¹³, and sensitisation to peripheral nerve basic proteins has been noted in GBS (refs 14, 15). Whether these sensitisations are primary or secondary features of the diseases is not known. Partly because signs of EAE can be suppressed by injections of CNS-BP and some other compounds¹⁶, trial treatment of MS with CNS-BP or other EAE-suppressive compound is being considered. In MS, IgG antibody is believed to be produced locally within the nervous system¹⁷. MS cerebrospinal fluid contains increased levels of oligoclonal immunoglobulins¹⁸ and increased numbers of IgG-containing cells¹⁹, both of unproven antibody specificity. If plasma cells specifically binding myelin basic proteins were present in MS or GBS, this would support the suggestion that sensitisation to myelin basic proteins may have a role in these diseases.

We have sought cells binding an HRP conjugate of CNS-BP in fresh frozen tissue obtained at autopsy from three chronic cases of MS. Formalin-fixed cryostat sections of nine cerebral MS plaques with adjacent white matter were stained with oil red O and methyl green-pyronin as well as with a light microscopic, peroxidase-CNS-BP conjugate procedure described previously⁷. All the plaques exhibited disease activity, as indicated by the presence of considerable numbers of fat-laden macrophages at the periphery, and four were quite active with lipid macrophages throughout.

Perivascular mononuclear infiltrates and scattered pyronophilic plasma cells, both within the cuffs and free in the parenchyma, were present in seven plaques. Two additional blocks of normal appearing white matter containing scattered pyronophilic mononuclear cells were also studied, as was one lymph node from the case with three of the most active plaques. In addition, we assayed smears of cerebrospinal fluid sediments containing mononuclear cells from four other MS patients and two controls. All these tissues and cells were incubated either with a conjugate of bovine or human CNS-BP, or both. Although these two conjugates both gave positive results in lymph nodes of rabbits immunised with bovine CNS-BP, in none of the MS tissues or cells was specific binding of CNS-BP demonstrable.

Fresh frozen tissue from two fatal cases of GBS was similarly tested, but in this instance for binding of an HRP conjugate of bovine P2 protein⁸. Formalin-fixed cryostat sections of five lumbar and three sacral DRG and two peripheral nerves generally contained mononuclear infiltrates and rare plasma cells, but no specific binding of P2 protein was found. The P2 protein conjugate did reveal positive plasma cells when used with lymph nodes and DRG from rabbits immunised with bovine peripheral myelin.

In contrast to the situation in EAE and EAN, these studies do not support the existence of sensitisation to basic proteins from myelin in either MS or GBS, as measured by cellular anti-basic protein antibody. Serum and cerebrospinal fluid anti-basic protein antibodies also are reported not to be detectable in MS^{20,21}. Since in both EAE and EAN, only a portion of the plasma cells bind basic protein conjugates, sampling of the human material could constitute a limitation of this study. Little is known about the species cross reactivity of P2 protein, but species differences are unlikely to be a factor in the MS results of this study. Both human and bovine CNS-BP were tested, and wide species cross reactivity between human, bovine, rabbit, rat and guinea pig CNS-BP has been demonstrated with this peroxidase procedure (A.B.J., unpublished observations) and by another technique²².

We thank Drs W. W. Tourtellotte, J. M. Powers, A. J. Spiro and F. H. Anlyan for some of the MS and GBS material and Drs E. H. Eylar and S. W. Brostoff for the purified basic proteins. We are particularly grateful to Dr R. D. Terry for his support and encouragement. Ms Norma R. Blum gave technical assistance. This work was supported by grants from the National Multiple Sclerosis Society.

Proposed respiratory 'gating' mechanism for cardiac slowing

THREE of the essential variables concerned in the regulation of systemic cardiovascular performance are cardiac output, blood pressure and the resistance encountered by the blood in flowing through the systemic vascular bed. Cardiac output may be further considered as the product of cardiac stroke volume and heart rate. The latter is under the control of the vagi and sympathetic nerves but the reflex bradycardia produced by vagal activation as a result of increased blood pressure, increased carotid chemoreceptor activity or direct electrical stimulation of the carotid sinus nerve occurs only if the stimulus is delivered during expiration. A sustained stimulus

Fig. 1 *a* and *b*, Spinal cord cut at level of first cervical vertebra; cat ventilated with respiratory pump. *a*, Pump switched off and sinus nerve stimulated producing bradycardia; *b*, pump switched off and sinus nerve subsequently stimulated during period of sustained lung inflation (between arrows); no bradycardia. *c*, Intact animal; natural breathing. Sustained lung inflation between arrows. Combined sinus nerve and superior laryngeal nerve stimulation begun during this inflation; only effective in producing bradycardia on deflation of lungs.

which is able reflexly to activate the cardiac vagal efferents will, therefore, produce the pattern of heart rate known as sinus arrhythmia (that is, a slow heart rate regularly interrupted by periods of cardiac acceleration coinciding with inspiration). This association of inspiratory activity with the inhibition of bradycardia is also seen when stimulating certain areas of the brain: areas which produce an inhibition of bradycardia^{2,3}

Fig. 2 Spinal cord sectioned at level of first cervical vertebra; cat ventilated with respiratory pump. Central inspiratory drive indicated by recurrent laryngeal electroneurogram. In *a* the pump is switched off and the sinus nerve stimulated at a strength that increases the intensity and frequency of the central inspiratory drive, which is clearly in phase with the periods of cardiac acceleration of the sinus arrhythmia. (The R_a neurones are then driving the R_b neurones?) In *c* the sinus nerve is stimulated at a reduced strength following a long period of artificial ventilation, and a bradycardia with much less sinus arrhythmia is seen. (The R_b neurones are perhaps less active under these conditions.) In *b* when the lungs are artificially ventilated with an increased stroke volume the periods of cardiac acceleration now correspond with lung inflation and not with the central inspiratory drive. (Possibly in these conditions the R_b neurones, which are powerfully provoked by artificial lung inflation, are insensitive to the natural R_a discharge.)

also produce an increase in respiratory activity, while other areas produce bradycardia and apnoea⁴. A vagal bradycardia unrelated to respiration can in fact only be induced by stimulating the cells of origin in the nucleus ambiguus^{5,6} or the vagus nerve itself. This nucleus lies in the medullary reticular formation ventro-lateral to the nucleus of the tractus solitarius. Since all known afferent stimuli which cause reflex bradycardia converge on the area of the nucleus tractus solitarius where "inspiratory" type neurones abound before passing on to the nucleus ambiguus, it is tempting to postulate that these inspiratory neurones may actually be part of a 'gate' which controls the passage of impulses through this reflex pathway. The rhythmical opening and closing of this gate with respiratory activity would result in sinus arrhythmia provided the gate remains open for a sufficient length of time and that there is an adequate background of vagal tone, which is in itself reflexly engendered. We have experimentally analysed some of the

properties of this proposed respiratory gating mechanism and conclude that it is in fact influenced by both neural inspiratory activity and by lung inflation.

Normally the central inspiratory drive and the resulting lung inflation are almost in phase with the inhibition of cardiac vagal tone. Both the central inspiratory drive and the resulting lung inflation may, however, be abolished by stimulation of the superior laryngeal nerve⁷ which inhibits the neural discharge to both inspiratory and expiratory muscles. If an adequate background level of afferent activity exists, such as is provided by baroreceptor discharge, bradycardia will occur as there is now no hindrance to the afferent impulse traffic to the nucleus ambiguus.

When both aortic and sinus nerves are cut, no bradycardia occurs on stimulation of the superior laryngeal nerve. This shows that stimulation of this nerve does not in itself induce bradycardia. If, in this preparation, the central end of a carotid sinus nerve is stimulated together with the superior laryngeal nerve, profound bradycardia occurs.

Although the superior laryngeal nerve is one of the most powerful means of opening the gate it is not in itself the "master key". If the lungs are kept artificially inflated, not even simultaneous stimulation of the sinus and superior laryngeal nerves produces bradycardia (Fig. 1c). As soon as the lungs are deflated this stimulation now provokes bradycardia.

After spinal transection at the level of C1, and with the lungs artificially ventilated, the vagal afferent traffic virtually becomes the only source of information concerning lung volume; in this situation, stimulation of the sinus nerve only elicits bradycardia when artificial respiration is discontinued with the lungs deflated (Fig. 1a and b). Thus inflation receptors may have a role in the genesis of sinus arrhythmia. It may be seen in Fig. 1a that, with the pump switched off, the heart rate is still being modulated by the central respiratory drive, and thus the onset of bradycardia provoked by sinus nerve stimulation is delayed by over 4 s presumably until the central inspiratory drive has temporarily ceased.

Fig. 3 Intact animal with open chest; ventilation of lungs with pump. Intercostal CMG to indicate central inspiratory drive. *a*, Pump stroke volume 75 ml; sinus nerve stimulation provokes sinus arrhythmia in which periods of cardiac acceleration correspond with central inspiratory drive and are not in phase with the pump. (R_b are being driven by R_a neurones and are insensitive to small volume high frequency ventilation.) *b*, Pump stroke volume 150 ml; periods of cardiac acceleration in sinus arrhythmia now correspond with lung inflation and are not in phase with central inspiratory drive. (R_b are driven by high volume low frequency lung inflation and are insensitive to natural discharge of R_a neurones.)

It is however also possible to show that in such spinal animals the central respiratory drive can by itself operate this 'gate' in the absence of lung inflation. In Fig. 2a artificial ventilation is temporarily discontinued during which time the sinus nerve is stimulated. In this circumstance sinus arrhythmia can still be observed with its periodic inhibition of bradycardia now in phase with the increased central respiratory drive. When artificial respiration is resumed, with an increased stroke volume bradycardia becomes associated with lung deflation rather than with the expiratory phase of the central respiratory rhythm (Fig. 2b).

Another method of dissociating the dual influence of central drive and lung inflation is to thoracotomise an otherwise intact anaesthetised animal and to ventilate its lungs with a pump. When the respiratory minute volume is adjusted to maintain normal values of pO_2 and pH at low tidal volume and high frequency, the central respiratory rhythm (recorded electromyographically from intercostal muscles) is slower than the prevailing pump frequency: sinus arrhythmia produced by sinus nerve stimulation now occurs in phase with this central rhythm (Fig. 3a). When tidal volume is increased and the rate of pumping slowed, so as to still preserve normal blood gas tensions and pH , the pump drives the central rhythm "out of phase", and now lung deflation occurs during central inspiratory drive: sinus arrhythmia produced by sinus nerve stimulation is now locked to the lung volume changes, with bradycardia in phase with lung deflation (Fig. 3b).

These results suggest the following propositions. (1) The gating mechanism, which may be complex, is probably located in association with both the nucleus tractus solitarius and with the nucleus ambiguus. (2) Complete inhibition of central respiratory drive, such as induced by stimulation of the superior laryngeal nerve, fully opens this 'gate' if, and only if, the lungs are in a state of deflation. (3) The gating mechanism can be operated independently by central drive or by lung inflation. (4) When the lungs are markedly inflated the pulmonary vagal afferent discharge is prepotent in closing the gate.

These considerations strongly suggest that a group of neurones first described by Baumgarten and Kanzow⁸ may qualify as an integral part of this gating mechanism. They described two types of inspiratory neurones in the vicinity of the nucleus tractus solitarius and named them R_a and R_b . The R_a neurones are centrally driven and discharge in phase with the phrenic motor neurones even when the respiratory muscles are paralysed with succinyl choline and both vagi are divided; these R_a neurones are inhibited by lung inflation. The R_b neurones discharge in phase with the R_a , even after succinyl choline and bilateral vagotomy, but unlike the R_a or the phrenic neurones, are stimulated by lung inflation.

R_a neurones do not fulfil the requirements necessary to operate as a gating mechanism as they do not discharge during lung inflation when the gate is shut. R_b neurones, on the other hand, do possess the necessary characteristics. Situated as they are, close to the nucleus tractus solitarius, they could operate in conjunction with the afferent stimulus, for it is known that the "gate" can function within one or two synapses of the afferent inflow⁶. They are independently or simultaneously driven both by central respiratory drive and by lung inflation and are correspondingly active in both situations of "gate" closure. It is possible that their extra discharge induced by powerful lung inflation leads to their becoming temporarily insensitive or 'refractory' to the central command. Such a characteristic might explain the occurrence, under special conditions, of bradycardia coincidental with central inspiratory drive but blocked by lung inflation (Figs 2b, 3b). Similarly after a period of powerful ventilation it is also possible, on suspending artificial ventilation and stimulating the sinus nerve, to induce bradycardia uninterrupted by the tachycardia normally associated with central inspiratory drive (Fig. 2c). Lipski, McAllen and Spyer¹⁰ have analysed the response of R_b neurones to chemoreceptor stimulation in artificially ventilated anaesthetised cats and while finding that the R_b neurones could

be driven by the chemoreceptors during inspiration (with closure of the proposed 'gate'), they also found that the discharge of the R_b neurones during sustained lung inflation was diminished by chemoreceptor stimulation. This might be due to the previously mentioned insensitivity of the R_b neurones to the central inspiratory drive associated with a period of sustained lung inflation and the unmasking of an inhibitory influence of the chemoreceptors on the R_b neurones. Such an influence would be clearly beneficial in the chemoreceptor-induced bradycardia that occurs when efferent respiratory activity is also suspended by simultaneous stimulation of the superior laryngeal nerve¹¹. The presence of ungated baroreceptor units in the vicinity of the nucleus ambiguus in no way negates the 'gating' hypothesis as the final inhibitory neurone of the gate mechanism may terminate directly on the cell bodies of the nucleus ambiguus.

The R_b neurones, therefore, appear as strong candidates for incorporation in the neuronal organisation of this proposed respiratory 'gate'.

Morphine, enkephalin and the substantia gelatinosa

THE pentapeptide enkephalin interacts with opiate receptors of peripheral tissues¹ and with stereospecific opiate receptors of brain homogenates². Ejected from micropipettes in the vicinity of central neurones, it has depressant³⁻⁵ and excitant⁶ effects. These actions, however, cannot be related specifically to the analgesic effects of systematically administered opiates. In electrophoretic experiments, tissue concentrations are unknown and hence even antagonism by electrophoretic naloxone is not necessarily a sufficient test of relevance to the effects of systemic opiates. This report is concerned with the effects of morphine when administered electrophoretically into the substantia gelatinosa. The subsequent changes in the firing of neurones within Rexed laminae IV and V can be related to the effects of this compound given systemically. Furthermore methionine enkephalin had an action similar to that of morphine.

Experiments were performed on cats anaesthetised with α -chloralose. The spinal cord was divided at the thoracolumbar junction. In preliminary experiments morphine (0.07 M) and naloxone (0.1 M, Endo Laboratories) were ejected electrophoretically from the outer barrels of 7-barrel micropipettes and the centre barrels were used for extracellular recording. Drug administration was thus largely into the region of cell bodies. Neurones of spinal laminae IV and V were excited alternately by radiant heat adequate to raise the skin temperature of a hind limb digital pad above 45 °C (a noxious stimulus), and

Fig. 1 The effect of morphine (*a*) and methionine enkephalin amide (*b*) on the firing of lamina IV spinal neurones by a noxious and non-noxious skin stimulus and the reversal of these effects by intravenous naloxone (0.1 mg kg^{-1}). In both *a* and *b* the noxious stimulus was heat to the fourth digital pad of the left hind leg adequate to raise skin temperature above 45°C ; the non-noxious stimulus was deflection of adjacent hairs by a moving air jet. In *a*, 14 min elapsed between the recording of the left and middle groups of responses and 55 min between the middle and right groups. In the latter interval, naloxone, ejected electrophoretically into the substantia gelatinosa, was shown to antagonise the effects of morphine. In *b*, 12 min elapsed between the right and left groups of records.

by deflection of the adjacent hairs by a moving air jet (a non-noxious stimulus). In these conditions morphine failed to reduce selectively the activation of cells by either stimulus, and high ejecting current (80–100 nA) produced abnormalities in action potential amplitude and configuration⁸.

In marked contrast, when morphine was ejected from another micropipette located superficial to the cell body and positioned in the region of the substantia gelatinosa, selective depression of cell responses to the noxious stimulus was observed without effect on those to the non-noxious stimulus (11 to 14 cells). The separation between the tips of the drug-administering and the recording micropipettes varied from 100 to 830 μm . Results from one neurone are illustrated in Fig. 1*a*. The middle records show that after 14 min of administration of morphine with an ejecting current of 150 nA, there was approximately a 50% reduction in the response to painful stimuli while the non-pain response was slightly increased. The reduction in the response to painful stimuli by morphine was long lasting, commonly greater than 30 min. This effect of morphine was reversed by naloxone administered electrophoretically in the substantia gelatinosa, and, more significantly, by intravenous naloxone in doses as low as 0.1 mg kg^{-1} . This dose of naloxone reverses the effects of analgesic doses of morphine in the cat⁹ and dog¹⁰ and its effectiveness in our experiments strongly suggests that the concentrations of morphine in the substantia gelatinosa reducing responses to painful stimuli were not inappropriate to those present after systemic morphine. The rapid effects of intravenous naloxone are shown in Fig. 1*a*.

Two samples of enkephalin were ejected from pipettes positioned in the substantia gelatinosa; methionine enkephalin (Calbiochem, 0.015 M, pH 3.5) and methionine enkephalin amide (supplied by Drs H. Niall and G. Tregear, The Howard Florey Institute, Melbourne; 0.020 M, pH 4). Of 17 cells tested, enkephalin ejected into the substantia gelatinosa reduced the responses of 12 to painful stimuli. With six neurones this reduction occurred in the absence of any effect on responses to painless stimulation or on spontaneous firing, with five the predominant effect was a reduction in the response to painful stimuli with a smaller reduction in the response to painless ones, and with one cell all three firing patterns were reduced in parallel. In the latter case the separation between the electrode tips was the smallest used. More consistent effects were observed with methionine enkephalin amide (10 of 11 cells tested) than with methionine enkephalin (2 of 6 cells). Figure 1*b* shows the selective reduction of the responses to painful stimulation of a lamina IV neurone after 13 min of ejection of methionine enkephalin amide (110 nA) in the substantia gelatinosa. In contrast to morphine, recovery from the effects of enkephalin was rapid, being complete within 10 min of the termination of ejection.

The reduction of responses to painful stimulation by enkephalin was fully reversed in 5 of 6 animals by a low dose of intravenous naloxone (0.1 mg kg^{-1} in four cats, and 0.3 mg kg^{-1} in one). The effect of naloxone was rapid as illustrated in Fig. 1*b*. All observed effects of enkephalin were reversed by naloxone—when response to non-painful stimulation and spontaneous firing were depressed by enkephalin this depression was also reversed by intravenous

naloxone. With one neurone, intravenous naloxone 0.1 mg kg^{-1} partially reversed the effects of enkephalin; this effect was not increased by additional doses up to a total of 1.2 mg kg^{-1} .

These results suggest that a receptor for morphine in the substantia gelatinosa is indeed relevant to the reduction, by systemic opiates, of pain with minimal effect on other sensations¹¹. The substantia gelatinosa contains the endings of primary afferent fibres, dendrites of deeper neurones, and small neurones which project only to other parts of the substantia gelatinosa. Axo-axonic synapses are abundant¹². Autoradiographic¹³ and binding studies¹⁴ have shown this to be a region of high opiate binding, but further experiments are needed to determine the fine structural localisation of the morphine receptors of the substantia gelatinosa and their relevance to primary afferent fibres and interneurons associated with painful stimuli. The methods used in the present experiments offer a means for determining the possible physiological role of enkephalin.

Intraventricular Met⁵-enkephalin causes unexpected lowering of pain threshold and narcotic withdrawal signs in rats

PEPTIDES with opiate properties have been demonstrated in brain^{1–3} and pituitary^{4–7}. Goldstein⁸ has postulated that sustained low-intensity pain might promote the central mobilisation of endogenous opioid as part of an adaptive response to noxious stimuli which cause suffering but do not threaten survival. We have examined the effects of intraventricular infusion of an endogenous opioid peptide, methionine-enkephalin⁹ (Met⁵-enkephalin), on responses to a sustained mildly noxious stimulus⁹ in rats. We expected Met⁵-enkephalin to attenuate responsiveness to the noxious stimulus, as has been reported¹⁰ for its effects on acute pain. On the contrary in our experiments, however, it seems to have increased responsiveness, and moreover to have induced behaviour typical of opiate withdrawal.

Thirteen male Sprague-Dawley albino rats, 180–200 g, were implanted under pentobarbitone anaesthesia (Nembutal, 50 mg kg⁻¹) stereotactically with chronic intraventricular cannulae in the right lateral ventricle (De Groot¹¹: A-3.2, L-5.0, V-5.1) according to the technique of Rezek and Havlicek¹². Correct placement of cannulae and success of infusion were confirmed histologically. Rats were first tested (test 1) 8 d after cannula implantation. They were given intraventricular infusions of either 10 μl saline over 65 s (saline control group of test 1) or of 100 μg Met⁵-enkephalin (Beckman Bioproducts) in an identical volume and rate of saline infusion. At 1.0 min after the end of

Fig. 1 *a*, Effect of Met⁵-enkephalin (stippled column and \blacklozenge) via right lateral ventricular infusion on hindpaw licks in rats kept on 44.5 °C hotplate for 10 min (test 1 of cross-over test). For a given group, each point on graphs indicates average number of hindpaw licks per animal observed over the minute preceding the plotted time. Height of arrowed horizontal lines above abscissa indicates hindpaw licks per min over last 7 min of the 10-min test; their vertical lines show standard errors. Six rats were infused with Met⁵-enkephalin, seven with saline (open column and \circ) as controls. Latency is time in s when first hindpaw lick was observed after rat was placed on hotplate; height of latency bar represents mean for each group. *b*, Test 2 of crossover test. Rats in Met⁵-enkephalin group ($n = 5$) were all taken from those in the saline group of test 1; rats in the saline group ($n = 4$) were all taken from those in Met⁵-enkephalin group of test 1. Other details as in *a*.

infusion the animals were placed within a vented transparent cylinder (48 cm high \times 20 cm in diameter with top open) on a hotplate at 44.5 °C (ref. 9). There was a significantly ($P \leq 0.01$) higher frequency of hindpaw licking in the Met⁵-enkephalin-infused group than in the saline controls, evaluated over the last 7 min of the 10-min test (Fig. 1*a*). Significant differences did not occur between hindpaw licking frequency in the two groups over the first 3 min, nor between latencies to the first hindpaw lick (Fig. 1*a*).

All animals with cannulae still intact after 5 d were retested (test 2) in crossover fashion; those which had received saline in test 1 were given infusions of Met⁵-enkephalin, and vice versa. Again, the Met⁵-enkephalin-infused group exhibited significantly ($P \leq 0.02$) more hindpaw licking than did the saline-infused rats (Fig. 1*b*), thus confirming results of the first test. Mean latency to first hindpaw lick was shorter in the Met⁵-enkephalin-infused rats in test 2 (Fig. 1*b*) than in the same animals during infusion with saline in test 1 (Fig. 1*a*). The difference was significant ($P \leq 0.05$) by single-tailed *t*-test for paired comparisons.

In both tests, all the animals infused with Met⁵-enkephalin exhibited signs of narcotic withdrawal¹³, that is: wet dog shakes, rearing, sniffing, restless exploring activity and increased defaecation, beginning at 1–3 min after the start of infusion. In some animals these signs were particularly severe. None of the rats showed these signs when infused with saline in either test.

Six of the rats used in tests 1 and 2 were retested on the hotplate, 7 d after test 2, with infusion of 2.0 μg naloxone hydrochloride (Endo Laboratories) in 10 μl saline/65 s. The animals showed significantly ($P \leq 0.05$) more hindpaw licking than did the saline-infused animals of either test 1 or 2 but displayed no signs of narcotic withdrawal. Retesting three of these animals with 15.0 μg naloxone 10 d later gave a similar result.

The hotplate test used here differs from the conventional hotplate test for analgesia in that the surface temperature is low enough to permit exposure of the experimental animal to a 10-min sustained mildly noxious environment in a demarcated space. It therefore permits observations to be made on the effects of drugs on the behavioural responses to such exposure; hindpaw licking is a prominent feature of those responses in rats. We believe it justified to regard hindpaw licking as an indication of pain, since it is readily distinguishable from

normal grooming activity and is much reduced by morphine given either intraperitoneally⁹ or intraventricularly. The effects of intraventricular Met⁵-enkephalin in causing an apparent increase in perception of pain, as well as signs of opiate narcotic withdrawal, were totally unexpected.

Leucine-enkephalin (Leu⁵-enkephalin) (Peninsula Laboratories) was tested in a separate series of experiments with 18 rats, also chronically implanted with intraventricular cannulae. Three groups of six rats were first tested after infusion of saline. In a second test 6 animals were given saline, morphine sulphate (10 µg), or Leu⁵-enkephalin (100 µg) (Fig. 2). It can be seen that morphine and Leu⁵-enkephalin significantly diminished hindpaw licking in response to the hotplate. Thus, Leu⁵-enkephalin, in contrast to Met⁵-enkephalin, exhibits analgesic action like that of morphine.

Our findings with Met⁵-enkephalin may be explained by three main factors: (1) inability of the pentapeptide opioid to reach sites of opiate analgesic action in caudal portions of the ventricular system¹⁴; such failure could be due to rapid destruction of Met⁵-enkephalin by brain peptidases¹⁵ and, perhaps, to poor lipid solubility; (2) excitation, by Met⁵-enkephalin, of sites of "paradoxical" opiate action^{16,17}; (3) the conditions of our hotplate test, which may induce the mobilisation and release of endogenous opiate-like substances in the brain, their target being stereospecific opiate receptor sites concerned with the attenuation of pain perception.

It is conceivable that among the released endogenous opioids there exists an unidentified opioid substance which is a more potent opiate agonist than Met⁵-enkephalin. After several minutes of stimulation by such an agonist, the system may adapt to, and thus become "dependent" on, the potent opioid; very rapid acquisition of opiate narcotic tolerance and physical dependence has been seen in several studies¹⁸⁻²⁰. The intraventricular infusion of Met⁵-enkephalin in such an opioid-

Fig. 2 Effect of Leu⁵-enkephalin (■), morphine (○) or saline (●) on rats subjected to a hotplate. Other details as in Fig. 1.

adapted brain would result in the displacement of the more potent endogenous opiate-like substance, with the consequent signs of narcotic withdrawal and hypernociception that we observed in our experiments. Studies³ on isolated organs *in vitro* have shown that Met⁵-enkephalin has predominantly opiate agonist properties. Nevertheless, its sodium sensitivity in opiate receptor binding studies⁷ suggests that Met⁵-enkephalin has at least some measure of opiate antagonist action, and the *in vivo* results described here indicate that Met⁵-enkephalin behaves as a mixed opiate agonist-antagonist. Our finding that

Leu⁵-enkephalin acts like morphine is compatible with *in vitro* data showing it to be a 'purer' agonist than Met⁵-enkephalin⁷. It may be that such mixed action of any opioid *in vivo* is simply the expression of the drug's relative ability both to displace endogenous opioid from opiate receptor sites and to act there itself. Failure of intraventricular naloxone (which aggravated pain but produced no signs of narcotic withdrawal) to behave identically with Met⁵-enkephalin might be due to differences in affinity between these substances for opiate receptors at sites differentially involved in the two behaviours. Aggravation of pain with parenteral naloxone at low doses has already been described^{21,22}.

Various endogenous molecular species^{1-7,23,24} may interact with the opiate receptor in response to noxious stimuli. Prominent among these is the C-fragment of β -lipotropin²⁵. The C-fragment molecule is 35 times as potent as Met⁵-enkephalin in displacing ³H-dihydromorphine; it has been reported to cause prolonged analgesia after infusion into the third ventricle of cat, and to show an analgesic potency, on a molar basis, 200 times that of morphine²⁵. Our present findings with intraventricular Met⁵-enkephalin and naloxone suggest that several endogenous opioids may be competing at multiple sites when mobilised during painful stimulation.

Enkephalin inhibits firing of myenteric neurones

ENDOGENOUS ligands for the opiate receptor have recently been described. The first to be characterised were methionine-enkephalin and leucine-enkephalin, pentapeptides isolated from porcine brain by Hughes *et al.* and subsequently synthesised¹. The enkephalins are also found in high concentrations in the myenteric plexus of the guinea-pig ileum^{2,3}, a neuronal network which is widely used as a model in investigations of narcotic action⁴. In the myenteric plexus, narcotic analgesics inhibit the neuronal firing which can be recorded with a glass suction electrode^{5,6}. This action is stereospecific, is reversed by narcotic antagonists such as naloxone and is not dependent upon the presence of any synaptic input to the neurones⁶. The endogenous presence of enkephalin in brain prompted an examination of its effects when applied by iontophoresis to units whose activity was recorded extracellularly⁷⁻¹⁰. We have adopted an alternative approach in which known concentrations of enkephalin are applied to isolated ganglia of the myenteric plexus whilst recording neuronal activity. The results indicate that low concentrations of the enkephalins act on the myenteric neurones to inhibit their firing.

Ganglia of the myenteric plexus, adherent to the longitudinal muscle layer, were perfused in a Krebs saline solution. Activity was recorded from single neurones with a glass suction electrode of 30–50- μ m tip diameter. The myenteric neurones are not spontaneously active within the isolated ganglia, but recently we have shown that the firing recorded with a suction electrode is initiated in the cell soma probably as a consequence of mechanical contact with the recording electrode (North and Williams, in prepara-

tion). In these conditions recordings can be made from single neurones for periods of several hours. The present results are based on recordings from 80 units in 20 guinea pigs. Both methionine-enkephalin and leucine-enkephalin caused an immediate inhibition of neuronal firing (Fig. 1). The depression of spike firing was dose-related; neuronal firing was often completely stopped by 100 nM Met⁵-enkephalin, and markedly inhibited by 10 nM. The firing rate increased immediately on washing with drug-free Krebs solution; in the majority of neurones the washout was associated with a transient but marked "rebound" increase in the rate of discharge (Fig. 1).

Met⁵-enkephalin was approximately five times more potent than Leu⁵-enkephalin when tested on the same unit (Fig. 1). Met⁵-enkephalin was five to ten times more potent than morphine or normorphine. When Met⁵-enkephalin is used to inhibit the nerve-mediated contractile response of the longitudinal muscle layer, it is approximately equipotent with morphine¹¹. However, in those experiments there is a relatively large piece of tissue whereas in our experiments there are only a few isolated ganglia. It is possible that the potency of enkephalin appears to be less in the experiments on the complete longitudinal muscle strip because a large proportion of the dose administered is bound nonspecifically and subsequently destroyed by peptidase. Further support for this notion derives from experiments in which we applied enkephalin for periods of several minutes. When the whole strip is used, the contractile response of the muscle begins to recover after about 1 min despite the continued presence of the enkephalin. However, the firing rate of a single neurone remained depressed for as long as 20 min when the tissue was perfused by a solution containing Met⁵-enkephalin (Fig. 1). There was no evidence of tachyphylaxis. The action of enkephalin was reversed or prevented by a tenfold lower concentration of naloxone (Fig. 2). this concentration of naloxone applied alone was

Fig. 1 Inhibition of firing of myenteric neurones by enkephalin. An isolated ganglion of the myenteric plexus was perfused with Krebs solution at 37 °C (solution composition (mmol l⁻¹): NaCl, 117; KCl, 4.7; CaCl₂, 2.5; MgCl₂, 1.2; NaHCO₃, 25; NaH₂PO₄, 1.2; glucose, 11.5; gassed with 95% O₂/5% CO₂). During the periods indicated by the horizontal bars the solution which perfused the tissue contained Met⁵-enkephalin or Leu⁵-enkephalin. *a*, Periods of exposure to Met⁵-enkephalin were 1, 2, 3, 4 and 10 min. In each case there was a marked inhibition of neuronal firing which reversed rapidly when the enkephalin application was stopped. *b*, A similar experiment on a different unit. Leu⁵-enkephalin (100 nM) had only a small and variable effect on cell firing, whereas Met⁵-enkephalin (100 nM) inhibited firing almost completely. The effect of Met⁵-enkephalin (100 nM) was similar to that of Leu⁵-enkephalin (500 nM). Notice in both experiments that there was no evidence of tachyphylaxis during exposures as long as 10 or 20 min. In these and other experiments, the "rebound" increase in firing rate when the enkephalin was washed out was more pronounced with longer periods of exposure.

Fig. 2 Effect of Met⁵-enkephalin and naloxone on the firing rate of a single myenteric neurone. During the periods indicated by the open and hatched bars, the solution which perfused the tissue contained Met⁵-enkephalin (100 nM) and naloxone (10 nM) respectively. Application of Met⁵-enkephalin for 3 min produced a complete inhibition of firing. This inhibition was rapidly reversed by changing to a solution which contained both Met⁵-enkephalin and a tenfold lower concentration of naloxone. In other experiments (for example Fig. 1) we have shown that the firing rate remains depressed by Met⁵-enkephalin even during prolonged applications. Naloxone itself was without significant effect on the firing rate, but it almost completely prevented the action of Met⁵-enkephalin. The final application of Met⁵-enkephalin to this neurone was probably somewhat reduced by the residual presence of some naloxone.

without effect on the firing rate. This finding substantiates the view that the enkephalin is acting on opiate receptors.

The technique which we have used offers certain advantages over the iontophoretic application of enkephalin *in vivo*. The precise concentration of enkephalin at the neurone is known, and degradation by tissue peptidase is largely avoided. Furthermore, as the cell firing is not dependent on synaptic input (ref. 6 and R.A.N. and J.T.W., in preparation), the enkephalins must be acting directly upon the neurone whose activity is recorded. The inhibition of firing by opiates was postulated to be due to a membrane hyperpolarisation⁶, and such an effect of morphine has recently been demonstrated by intracellular recording^{12,13}. The inhibition of neuronal firing by enkephalin may also be based on a membrane hyperpolarisation (R.A.N., unpublished). Inhibitory synaptic potentials have not been recorded in the myenteric plexus, and the role of enkephalin in this tissue remains obscure. On the other hand, if enkephalin inhibits the firing of central neurones by a similar mechanism then its candidacy as inhibitory transmitter would be supported.

We thank Dr B. A. Morgan, Reckitt and Colman Ltd, for a gift of Leu⁵- and Met⁵-enkephalin, Dr E. L. May for a gift of normorphine and Endo Laboratories for a gift of naloxone. The work was supported by a US Public Health Service grant.

Gonadotropin-releasing hormone surge in pro-oestrous rats

It has generally been accepted that the pre-ovulatory surge of luteinising hormone (LH) is caused by an increased release of gonadotropin-releasing hormone (GnRH) from nerve terminals in the median eminence. So far, however, estimations of the concentrations of GnRH in hypophyseal portal vessel blood by bioassay¹ or radioimmunoassay^{2,3} have failed to demonstrate a surge of GnRH before or during the spontaneous surge of LH. The anaesthetics used (urethane^{1,3} and sodium pentobarbitone²) block ovulation, and, therefore, are likely to block or truncate a surge of GnRH, if it occurs. We have re-examined this problem using Althesin (Glaxo, Middlesex) an anaesthetic which consists of 9 mg alphaxalone (3 α -hydroxy-5 α -pregnane-11,20-dione) and 3 mg alphadolone acetate (21-acetoxy-3 α -hydroxy-5 α -pregnane-11,20-dione) per ml of isotonic aqueous vehicle and show that it does not block the spontaneous LH surge or ovulation. Previous studies on the cat⁴ suggested that, although it can provide adequate analgesia, Althesin does not interfere with various forebrain functions.

All experiments were carried out on female Wistar rats, 200-300 g body weight, which were maintained under controlled lighting (lights on 0500-1900) and temperature (22 °C), and exhibited regular 4-d oestrous cycles. The animals were given free access to Diet 41B (F. Dixon & Sons, Ware) and tapwater. A dose of 0.5-0.6 ml Althesin per 100 g body weight, administered intraperitoneally, produced adequate analgesia (no somatomotor response to painful stimuli) for 2.0-3.5 h. Supplementary doses of 0.25-0.5 ml could be given at 2.0-h intervals without risk of fatality.

To test the effect of Althesin on ovulation and LH release, 14 rats were anaesthetised at 1330 on the day of pro-oestrus, and blood samples (0.3 ml) were taken from the external jugular vein either at 1800 ($n = 8$) or 5, 30 and 60 min ($n = 6$) after injection. Inspection of the oviducts on the following morning (expected day of oestrus) revealed that ovulation occurred in all the animals (mean \pm s.e.m. ova count per animal = 8.6 ± 1.0). The mean \pm s.e.m. concentration of LH, estimated by radioimmunoassay^{5,6}, in the samples taken at 1800 was 25.0 ± 8.8 ng NIH-LH-S18 ml⁻¹. Although lower than those in unanaesthetised animals or in animals anaesthetised immediately before blood withdrawal⁶⁻⁸, these results showed that, in contrast to sodium pentobarbitone and urethane, Althesin administered before the 'critical period' of pro-oestrus⁹ did not block the spontaneous surge of LH or ovulation. The plasma LH concentrations of the blood samples taken 5, 30 and 60 min after Althesin injection were 3.4 ± 0.5 , 3.1 ± 0.3 and 3.4 ± 0.3 ng ml⁻¹ respectively, indicating that Althesin does

Significance of differences between means as determined by analysis of variance and multiple range test:

 $P < 0.05$: group 10 compared with groups 4 and 21; group 11 compared with groups 3, 4, 8 and 21; group 12 compared with groups 1, 3–5, 7, 8, 20 and 21; group 14 compared with group 18. $P < 0.01$: group 13 compared with group 12. $P < 0.005$: group 13 compared with groups 10 and 11; group 14 compared with groups 9, 15 and 17. $P < 0.001$: group 13 compared with all groups except 10–12 and 14; group 14 compared with groups 1–8, 16 and 19–21.

not stimulate LH release. A possible progesterone-like action of Althesin was also tested (for rationale see ref. 10) in long term ovariectomised rats which had been given 20 μ g oestradiol benzoate, subcutaneously, 72 h before the administration of either 0.5 ml Althesin per 100 g, 2.5 mg progesterone or 0.5 ml arachis oil. Under ether anaesthesia, 5 h later, a blood sample was taken from the external jugular vein. The mean (\pm s.e.m.) plasma LH concentrations were 18.2 ± 6.2 , 35.8 ± 13.8 and 147.5 ± 35.4 ng ml⁻¹ in animals treated with oil ($n = 6$), Althesin ($n = 6$) and progesterone ($n = 7$), respectively. There was no significant difference between the mean plasma LH concentration in the oil, compared with the Althesin-treated group; however, the concentration in the progesterone-treated animals was significantly greater than that in oil- ($P < 0.005$) or Althesin- ($P < 0.02$) treated animals.

The concentration of GnRH in pituitary stalk blood was studied in 132 animals anaesthetised at frequent intervals during the oestrous cycle. The pituitary stalk was exposed according to Worthington¹¹ and Fink and Jamieson³. Special care was taken to ensure haemostasis; in particular, damage to the tuberoinfundibular artery was avoided whenever possible. Blood was collected during 3–6 consecutive 30-min periods and plasma GnRH concentration was determined by double antibody radioimmunoassay^{3,12,13}. The lower limits of sensitivity of

these assays for 100- μ l samples (mean c.p.m. -2 s.d. of the total bound tubes) ranged from 6.2 to 15.8 pg GnRH ml⁻¹. These values were assigned to the relatively few samples (see Tables 1 and 2) in which the concentration of GnRH was below the limit of sensitivity of the assay. For statistical purposes, the GnRH concentrations of the 30-min collections between various times of the cycle were grouped together to determine the mean concentrations shown in Table 1. Details of the GnRH concentrations in the 30-min collections are shown in Fig. 1. There were no appreciable differences between the mean GnRH concentrations on the days of metoestrus and dioestrus, and between 0800 and 1500 of pro-oestrus. Concentrations then rose to reach a value at 1730–1800 which was significantly greater than that at any other time except between 1800 and 1830. The decline in concentration which occurred after 1830 of pro-oestrus was interrupted by a small peak between 2230 of pro-oestrus and 0200 of oestrus. There were no significant differences between the volumes of the collections between 1030 and 1830 of pro-oestrus and between 2230 of pro-oestrus and 0200 of oestrus. Table 2 shows that the GnRH concentration of pituitary stalk blood collected during Althesin anaesthesia between 1600 and 1830 of pro-oestrus was significantly greater ($P < 0.05$) than the concentration in stalk blood collected at the same time from animals anaesthetised with sodium pentobarbitone. The

†As for Table 1.

Fig. 1 Mean (\pm s.e.m.) concentrations of GnRH (a) and volumes (b) of 30-min collections of pituitary stalk blood. Most means are based on 5–15 samples, a few on 3–4 samples. The mean concentrations of plasma LH (---) (data from ref. 6, with permission) are shown for comparison.

difference between the volumes of the collections was not significant. The concentration of GnRH in stalk plasma collected under Althesin was also greater ($P < 0.05$) than that in blood collected from the pharyngeal mucosa (for method see ref. 3) and in blood withdrawn from the external jugular vein ($P < 0.01$).

Comparison of the present data with peripheral plasma LH concentrations in rats of the same strain similarly maintained (Fig. 1) suggests that the LH surge begins shortly after the GnRH surge. After the peak, plasma LH concentrations fall in parallel with stalk plasma GnRH concentrations. The large variation in GnRH concentration, especially between 1600 and 1830 (values ranging from undetectable to 950 pg ml^{-1}) may be due to a pulsatile release of this hormone. Similar concentrations of GnRH in pituitary stalk blood have also been found around the mid-cycle of rhesus monkeys anaesthetised with phencyclidine hydrochloride¹⁴.

The smaller peak of stalk plasma GnRH concentration between 2230 of pro-oestrus and 0200 of oestrus may be related to the pre-ovulatory surge of plasma FSH which continues to rise after the cessation of the LH surge and reaches a peak at about 0500 of oestrus^{6,15}. This peak of GnRH concentration also occurs at about the time of maximal sexual receptivity¹⁶ and immediately precedes ovulation (0200–0400 of oestrus).

It has been established that in the rat and other spontaneous ovulators including man, there is a massive increase in the responsiveness of the anterior pituitary gland to GnRH which occurs before and during the pre-ovulatory surge of LH^{6,17}. The present results reveal the importance of this increase in pituitary response, for, even allowing for a twofold dilution of pituitary stalk collections by blood from sources other than the hypothyseal portal vessels¹, the mean concentrations of GnRH between 1600 and 1830 on the day of pro-oestrus are relatively low compared with a level of about $3,000 \text{ pg ml}^{-1}$ in the peripheral circulation, which is achieved 1 min after the intravenous injection of 50 ng synthetic GnRH per 100 g body weight¹³ (minimal ovulatory dose⁶). Intravenous infusion and multiple injection studies (ref. 13 and N.M.S., S.A.C. and G.F., unpublished) have shown that plasma GnRH concentrations of $100\text{--}400 \text{ pg ml}^{-1}$ are capable of producing a surge of LH on the afternoon of pro-oestrus provided that the pituitary is exposed to these levels for at least 30 min. Similar concentrations of plasma GnRH produce only a slight rise in plasma LH on the afternoon of dioestrus¹³. Thus, without the 50-fold increase in pituitary responsiveness to GnRH between 1330 on the day of dioestrus and 1730 on the day of pro-oestrus⁶ the spontaneous LH surge may not occur. The priming effect of GnRH¹³ which is activated by the increased secretion of GnRH during the afternoon of pro-oestrus may be responsible for ensuring that the peaks of responsiveness and the GnRH surge coincide.

Synthesis of luteinising hormone releasing factor and thyrotropin-releasing factor in glutamate-lesioned mice

The arcuate nucleus (ARC) of the mammalian hypothalamus is thought to regulate tonic luteinising hormone (LH) secretion from the anterior pituitary¹. But the immunohistochemical demonstration of luteinising hormone

releasing factor (LHRF) in nerve fibres but not cell bodies of the ARC^{2,3} and the marked reduction in LHRF content after hypothalamic deafferentation⁴, suggest that the ARC is not a centre for LHRF synthesis. To clarify this issue we have used monosodium glutamate, a neurotoxin which when administered in a low dose to young animals selectively destroys ARC neurones while leaving intact axons passing through⁵⁻⁷. If the ARC perikarya synthesise LHRF, a marked reduction in the immunohistochemical staining and content of hypothalamic LHRF should be evident in glutamate-lesioned animals. Because thyroid function is unaffected by glutamate⁸, we examined brain tissue for thyrotropin releasing factor (TRF) content as a control for the LHRF studies.

Ten-day-old CD1 albino mice (Charles River) received a single injection of glutamate (subcutaneous 18 mmol per kg body weight in a 10% aqueous solution), and their litter mate controls received an equal dose of NaCl. All animals were decapitated 96 h later. By this time, orthograde degeneration and phagocytosis of tubero-infundibular axons would be expected to be complete in the median eminence (ME) and stalk median eminence (SME)⁹. Brains from seven experimental and five control animals were removed rapidly. The hypothalamus was excised and extracted in 1 ml of 2N acetic acid. The remainder of the brain was extracted in 2 ml of 2 N acetic acid. An aliquot was removed for measurement of protein concentration¹¹. An aliquot (0.3 ml) of the remainder was freeze dried, redissolved in 0.01 M phosphate-buffered saline, pH 7.4, and assayed for LHRF using a radioimmunoassay with a sensitivity of 2 pg (I.M.D.J. and S. Reichlin, in preparation). Briefly, LHRF was labelled with ¹²⁵I using chloramine T and purified on a column of Sephadex G-25. The sample, ¹²⁵I LHRF and anti-LHRF at a titre of 1:96,000 were incubated for 48 h, and bound hormone was separated from free hormone with dilute charcoal. Antibody to LHRF was raised in a rabbit immunised with synthetic LHRF conjugated to bovine thyroglobulin, by means of *bis*-diazotised benzidine, similar to that used to develop anti-TRF¹². The LHRF antiserum reacted with the LHRF decapeptide as well as with certain C-terminal fragments (nonapeptide through pentapeptide). No cross-reaction occurred with the deamidated free acid form of LHRF, TRF, somatostatin, vasopressin, thyroid or anterior pituitary hormones. Hypothalamic and extrahypothalamic TRF in the same specimens were measured by a sensitive and specific radioimmunoassay for TRF¹².

In glutamate-treated animals there was a marked reduction in the number of neuronal cell bodies within the ARC (Fig. 1). Reaction product localising immunoreactive LHRF, however, was abundant and seen throughout the rostro-caudal extent of the ME and in the upper SME, as well as in the organum vasculosum of the lamina terminalis. Similar to the distribution described in adult mammals^{2,13}, immunoreactive LHRF in glutamate-lesioned mice tended to accumulate at the tubero-infundibular sulci, and to become more intensely concentrated in caudal regions just proximal and just distal to the SME. There was no difference in staining pattern or intensity compared with

Fig. 1 Light micrograph ($\times 46$) of a frontal section through the basal hypothalamus comparing the experimental (*b*) with the control (*a*) and demonstrating intense reaction product of immunoreactive LHRF at the tubero-infundibular sulci (arrows). Note marked reduction ($> 80\%$) in the size of the arcuate nucleus (ARC). ME, median eminence; III, third ventricle.

controls. In no instance was immunoreactive LHRF seen within ARC perikarya of either NBF or Bouin's fixed tissues.

Hypothalamic LHRF content of glutamate-treated mice (mean \pm s.e.m.), $1,275 \pm 106$ pg LHRF per hypothalamus ($7,734 \pm 1,389$ pg LHRF per mg protein), was similar to that seen in controls, $1,371 \pm 343$ pg per hypothalamus ($7,493 \pm 2,427$ pg LHRF per mg protein) (Table 1). In both experimental and control animals, extrahypothalamic LHRF content was very low, being at or just below the limits of sensitivity of the assay. Like LHRF, hypothalamic TRF content did not differ significantly between glutamate-treated ($2,178 \pm 165$ pg TRF per hypothalamus) and control ($2,532 \pm 159$ pg TRF per hypothalamus) animals. But TRF was readily measurable in considerable quantity in the extrahypothalamic brain of both groups (glutamate: $3,601 \pm 178$ pg TRF, control: $3,417 \pm 144$ pg TRF). These differences were not significant.

This study provides evidence that glutamate-sensitive ARC neurones do not give rise to the LHRF immunoreactive pathway, for glutamate-induced lesions, which destroyed most ARC neurones, neither altered the quantity and distribution of immunohistochemically demonstrable LHRF in the ME nor decreased total hypothalamic LHRF content. Therefore large concentrations of LHRF in the ARC, as determined by Palkovits *et al.*¹⁴, probably reflect the content of dense cored vesicles within fine calibre axons that course among ARC perikarya. Such LHRF-containing axons may also explain observations^{2,3} that immunoreactive LHRF fibres can be traced to the ARC. Their origin from

Table 1 Effect of monosodium glutamate on the hypothalamic and extrahypothalamic content of LHRF and TRF in mice (mean \pm s.e.m.)

	LHRF		TRF	
	pg per tissue	pg per mg protein	pg per tissue	pg per mg protein
Hypothalamus				
Glutamate	$1,275 \pm 106$	$7,734 \pm 1,389$	$2,178 \pm 165$	$12,914 \pm 1,637$
Control	$1,371 \pm 343$	$7,493 \pm 2,427$	$2,532 \pm 159$	$13,393 \pm 2,297$
Extra-hypothalamic brain				
Glutamate	< 66	< 18.5	$3,601 \pm 178$	829 ± 68
Control	< 66	< 16.3	$3,417 \pm 144$	840 ± 57

ARC perikarya, however, need not be imposed. Furthermore, many workers have failed to confirm^{2,13,15-17} reports that mammalian ARC perikarya are immunoreactive for LHRF¹⁸⁻²⁰, and it has been suggested that perikaryal staining described in these ARC is due to a nonspecific tissue-immunoglobulin reaction^{2,17}.

The data reported here suggest that the LHRF in the ARC region of mice is located in dense cored vesicles of axons passing through the nucleus, though its presence within the small number of ARC perikarya, which are not glutamate-sensitive in the conditions of the experiment, is not excluded. Further study of the origin of the immunohistochemically demonstrable LHRF-positive fibres in the ME and upper SME is needed.

We thank Ms Judith Bollinger and Ms Faye Soohoo for assistance with radioimmunoassays. This study was supported by a USPHS training grant.

Impairment of luteinising-hormone release following oestrogen administration to hyperprolactinaemic ewes

THE antagonistic role of prolactin during the post-partum period seems well established in many species¹⁻³. But mechanisms by which prolactin may act are not yet known. There is some evidence that prolactin may exert its inhibitory function at the ovarian level^{4,5}, but an eventual action on the hypothalamo-hypophysial axis cannot be excluded. Experiments described here have been designed to resolve this problem.

The responsiveness of the pituitary to luteinising hormone releasing hormone (LHRH) injections, was studied in eight suckling 'Préalpes du Sud' ewes. All the animals were spayed in October, 1 d after parturition, to eliminate the variable of ovarian steroid feedback. Four of the ewes were given 1 mg 2-Br- α -ergocryptine (CB 154, Sandoz) intramuscularly, twice daily from

Fig. 1 LH increments in spayed ewes after intravenous injection of 200 μ g LHRH (arrow): \bullet , control ewes; \square , TRH-treated animals. (Mean values \pm standard error. Four animals in each group.)

the time of parturition to day 60 *post partum* to suppress prolactin levels⁶. The other four animals served as untreated controls with high prolactin levels. Ovine prolactin and LH were measured by radioimmunoassay^{7,8}.

Both groups were injected once a week for eight weeks with an intravenous bolus of 200 μ g synthetic LHRH (Hoechst) and an LH release was always observed in all animals. The responses were very weak on the day of parturition (before castration), but increased progressively during the first four weeks *post partum* and remained constant thereafter. Since the pattern of LH release was indistinguishable in the treated and control group, it was concluded that high prolactin levels do not modify the ability of the pituitary to discharge LH in response to LHRH.

Fig. 2 Inhibition during hyperprolactinaemia of LH release attributable to oestradiol-17- β in three spayed ewes. \bullet , control ewes; \square , TRH-treated animals. Arrows, intramuscular oestradiol-17- β : a, 25 μ g; b, 25 μ g; c, 12 μ g.

A similar experiment was performed on a group of spayed ewes that were not lactating. Intravenous LHRH (200 μ g) was given twice at 3-d intervals, on the first occasion during a control infusion with physiological saline, and the second during a time when prolactin levels had been artificially elevated by repeated infusions of thyrotropin releasing hormone (TRH), 20 μ g, 12 times a day. This produced an elevated prolactin level 48 h before the LHRH stimulation, and mimicked the suckling-induced prolactin surges⁹. Once again, the LH response to exogenous LHRH was not modified by the hyperprolactinaemia (Fig. 1). These results are also in agreement with observations on women in hyperprolactinaemic amenorrhea¹⁰⁻¹², where the LHRH response was normal. Hyperprolactinaemia in the monkey may, however, render the pituitary less responsive to LHRH¹³.

To see whether the positive feedback effect of oestradiol on the hypothalamus was impaired by high prolactin levels, ewes castrated for more than three months received at 48-h intervals three

randomised intramuscular injections of oestradiol-17- β (12, 25, 50 μ g). The most effective dose in terms of gonadotropin release differed from one animal to another. This dose of oestradiol-17- β became ineffective after the same animal had been rendered hyperprolactinaemic with TRH infusions, as described previously (Fig. 2).

These findings, together with recent data from women^{14,15}, suggest that the positive feedback effect of oestradiol on LH release^{16,17} is greatly impaired by high prolactin levels. This is probably one of the ways in which suckling inhibits ovulation.

We thank Dr R. V. Short for criticism and Mrs C. Meusnier for technical assistance. This work was supported by grants of the Délégation Générale à la Recherche Scientifique et Technique and of the Institut National de la Santé et de la Recherche Médicale.

Implantable artificial endocrine pancreas unit used to restore normoglycaemia in the diabetic rat

PARENTERAL insulin therapy has long been the primary form of treatment for patients with diabetes, but it does not prevent the chronic complications of diabetes, which involve retinopathy, neuropathy, nephropathy and vascular disease and cause the most morbidity and mortality of diabetic patients. One of the most promising alternative approaches involves transplantation of insulin-producing tissue. In animal models, sustained correction of diabetes has been accomplished by the transplantation of isolated pancreatic islets from donors syngeneic with the recipients^{1,2}. We report here experiments with an implant in which islet cells are placed outside a synthetic capillary (hollow fibre) through which smaller molecules, such as insulin, can diffuse freely. Using this device we have normalised the high glucose level of diabetic rats.

The capillary consisted of a polyvinyl chloride-acrylic copolymer (XM-50) fibre (Amicon) with a 450- μ m internal diameter which had a nominal molecular weight cutoff of 50,000. A 2.8-cm long fibre was connected by epoxy resin at both ends with 5-cm pieces of radiopaque intravenous catheter with a 0.81-mm internal diameter and 1.2-mm outside diameter (Venocath-16, Abbott). The fibre was inserted into 3 cm of polyethylene shell (Intramedic Tubing, PE320, Clay Adams, B.D. and Co., Parsippany, New Jersey) and the implantable artificial capillary unit was made by sealing the lumen of the polyethylene shell and the fibre at the fibre-catheter junction (Fig. 1).

Islets of Langerhans were isolated from male Wistar rats

Fig. 1 Diagram to show the construction of the implantable artificial endocrine pancreas.

(310-330 g) by collagenase digestion³ and purified by Hypaque-Ficoll density gradient centrifugation⁴. Between 1,200 and 1,500 intact islets were suspended in Medium 199 supplemented with 10% foetal calf serum, penicillin (100 U ml⁻¹), streptomycin (0.1 mg ml⁻¹) and kanamycin (0.1 mg ml⁻¹) and were introduced into the artificial capillary unit through two 0.12-cm holes in the polyethylene shell. The holes were plugged with 'fitted rubber' tips (Critocap-J, Sherwood Medical Ind. Inc., St Louis) and sealed with epoxy resin.

This implantable artificial endocrine pancreas unit was perfused overnight with 125 ml of nutrient medium which was recirculated at a rate of 1.5-2.0 ml min⁻¹. Silastic tubing connecting the unit and the medium reservoir served as a gas exchanger. The circuit was operated at 37 °C in a humidified atmosphere of 5% CO₂ and 95% air.

We used male inbred Lewis rats, in which diabetes was induced by intravenous injection of streptozotocin (5.5 mg per 100 g) when they were between 300 and 320 g in body weight. An animal was defined as diabetic only when 24-h urine outputs were greater than 100 ml for at least 2 weeks and when the fasting blood glucose level was greater than 400 mg per 100 ml. Twenty-four hours before implantation, a radiopaque intravenous catheter (Venocath-16) was inserted into the jugular vein of the recipient diabetic rat to facilitate collection of blood samples, the infusion of heparin and the replacement of isogenic blood during the subsequent experiment. The catheter was kept open with saline containing heparin (10 U ml⁻¹). The diabetic rat was fasted for 4 h before implantation which was carried out under ether anaesthesia. An incision 3 cm long was made along the linea alba and the abdominal aorta was exposed. Heparin (50 U) was injected intravenously through the femoral artery. Two clamps were applied on the abdominal aorta between the renal artery and the ilio-lumbar artery. The implant was subsequently inserted directly into the abdominal aorta.

Fig. 2 Radiogram to show the positioning of the jugular vein catheter for blood sampling and the site of the implanted artificial endocrine pancreas as a vascular shunt in the abdominal aorta.

Samples of 0.4 ml of blood were withdrawn before the ether anaesthetic, every hour for the first 5 h after implantation and every other hour thereafter, for blood glucose and insulin determinations (by the Beckman glucose analyser and the insulin assay kit (Amersham Searle), respectively). Withdrawn blood was replaced with isogenic blood. To maintain the circulation through the implanted unit, the recipient was administered 50 U of heparin at 2-h intervals for the first 8 h and subsequently with 100 U of heparin every 4 h.

Fig. 3 Decline in blood glucose levels in diabetic rats after the implantation of an artificial endocrine pancreas. Pre indicates the sample taken before ether anaesthesia for the implantation procedure. Time 0 represents the connection of the artificial endocrine pancreas as a shunt in the circulatory system. The values expressed are the $\bar{X} \pm \text{s.e.}$ blood glucose and insulin levels of eight diabetic rats receiving such implants.

The positioning of the jugular vein catheter and the implanted artificial endocrine pancreas are shown radiologically in Fig. 2. In all the recipient streptozotocin-induced diabetic rats blood sugar levels started to decline within 2 h and achieved normoglycaemia between 4 and 5 h after implantation. There was a corresponding increase in blood insulin levels.

Figure 3 shows the trend of changes in blood glucose and circulating insulin in eight diabetic rats receiving

Fig. 4 The blood glucose and insulin levels in diabetic rats following the implantation of an artificial endocrine pancreas (—), and in diabetic rats following the implantation of an artificial capillary unit without islets (---). Each point represents the average value for two animals.

implants. The limited duration of study in this group was a consequence of excessive bleeding due to the effect of heparinisation. Figure 4 shows changes in insulin and blood sugar in two recipients which survived longer after implantation. Two diabetic control rats, given a capillary unit without islets, showed persistent hyperglycaemia and low insulin levels. There was clearly an improvement of hyperglycaemia and increased circulating insulin levels in diabetic rats after implantation with functional islets inside the artificial capillary unit.

We have shown already that the functional capacity of intact islets cultured in artificial capillary culture units *in vitro* is maintained for at least 97 d (ref. 5). Cultured islets responded to increased glucose concentration by increased insulin production throughout the culture period and the maintenance of the functional capacity of islets within the artificial capillary unit *in vivo* may also be anticipated. Although the *in vivo* studies were of limited duration, our results show that the implanted unit is sensitive to glucose and can produce sufficient insulin to normalise the high blood sugar levels in the diabetic rats within 4 h of implantation.

The potential importance of this approach is to provide functional pancreatic islets in the diabetic recipient which can supply insulin, glucagon and possibly other islet factors, in response to physiological needs and ultimately ameliorate insulin-requiring diabetes and perhaps prevent the development of complications. Islets within the unit may be protected from immune destruction by circulating host lymphocytes and antibodies, by virtue of the selective permeability of the molecular size of the synthetic capillaries. Thus, the artificial endocrine pancreas unit would mimic an immunologically privileged site. The system, if successful in the allogeneic rat, would have clinical potential.

Carbocyanine dyes inhibit Ca-dependent K efflux from human red cell ghosts

CARBOCYANINE dyes are fluorescent probes of membrane potential in red cells^{1,2}, and their application has been extended to Ehrlich ascites cells^{3,4} and phytoplankton⁵. I have used them to study the effect of potassium concentration gradients on the membrane potential of resealed ghosts containing Ca buffers. Intracellular Ca specifically renders these ghosts highly permeable to K (ref. 6). During this work, I discovered that 3,3'-dipropyl- and 3,3'-diethylthiadicarbocyanine iodide cause a progressive inhibition of K efflux at low external K concentrations, and that external K protects against the inhibitory effects of the dyes. The results suggest that the carbocyanine dyes are specific inhibitors of the Ca-dependent K transport system.

response was a large hyperpolarisation, followed by a rapid depolarisation to zero potential. Such a depolarisation might be caused by an equalisation of internal and external K, an increase in Cl permeability or a decrease in K permeability. Subsequent addition of $1\text{ }\mu\text{M}$ valinomycin (arrow V) caused a large hyperpolarisation, indicating that a large K gradient was still present. The (dipropyl) dye greatly reduces the rate of loss of K from the ghosts (Fig.2), so the depolarisation seen in Fig. 1c is caused by a decrease in K permeability. Figure 1d and e shows that a similar response is seen in solutions containing 0.1 mM K and 0.5 mM K, but the rate of depolarisation is reduced as the K concentration is raised. In Fig. 1f the ghosts were suspended in a 0.1-mM K solution, but the K concentration was increased by 2 mM during the depolarising phase (arrow K). This prevented further depolarisation, and the membrane potential was held at an intermediate value. Subsequent addition of valinomycin again produced a large hyperpolarisation. Similar experiments (not illustrated) showed that Rb and Cs ions are also able to prevent the depolarisation seen in low K solutions, whereas Na, Li, choline and tetraethylammonium ions are ineffective. This is the same cation selectivity as that of the Ca-dependent K transport system⁷. It seems likely that the depolarisations seen in Fig. 1 reflect a specific association between the dye and the K transport system, and the antagonistic effect of external K suggests that the reaction occurs at the external surface of the membrane. The specific nature of the interaction is confirmed by the lack of effect of the

	Ouabain -	Ouabain +
Dye -	0.94 ± 0.05	0.06 ± 0.02
Dye +	0.90 ± 0.03	0.04 ± 0.01

Washed human red cells (blood bank) were suspended at 37 °C, haematocrit 0.7%, in a solution containing 150 mM choline Cl, 8 mM Tris Cl, 2 mM Tris phosphate, 5 mM glucose and 0.16 mM ^{42}KCl (pH 7.3). When present, ouabain was at 70 μM and the dye at 300 nM. For each condition, samples were taken in triplicate at 0, 20, 40 and 60 min, centrifuged, and the cells washed three times in ice-cold incubation medium lacking ^{42}K . The influxes (in mmol per l cells h^{-1} , \pm s.d.) were calculated from plots of the radioactivity in the cells against time.

dye on the Na pump-catalysed influx of K into red cells suspended in a 0.16-mM K medium (Table 1).

The experiments illustrated in Figs 1 and 2 monitor a changing situation during the onset of inhibition. Not only is the degree of inhibition increasing, but the internal and external dye concentrations are changing during this period⁸. In spite of this, a rough dose-response curve (Fig. 3), constructed from a series of observations of K efflux rates, shows 50% inhibition of K efflux by about 20–50 nM 3,3'-diethylthiadicarbocyanine iodide at 0.1 mM external K. This is likely to be an overestimate of the half-inhibition constant because the measurements were made during the onset of inhibition, rather than at equilibrium.

Fig. 3 Dose-response curve for the inhibition of net K efflux by 3,3'-diethylthiadicarbocyanine iodide. Each point gives the weighted mean of two determinations, from measurements made as in Fig. 2. To make a quantitative estimate of the rate of K efflux it was assumed (incorrectly) that external K would approach its equilibrium value exponentially, and the rate constants obtained from the slopes of straight lines fitted to plots of log (fraction of K remaining in ghosts) against time.

Preliminary experiments have also shown that, at fixed dye concentrations of 400 nM, 3,3'-diethylthiadicarbocyanine iodide and 3,3'-diethylthiatricarbocyanine iodide are as effective as 3,3'-diethyl- and 3,3'-dipropylthiadicarbocyanine iodide in inhibiting net K efflux from Ca-containing ghosts, whereas 3,3'-diethyloxycarbocyanine iodide and 3,3'-diethyl-9-ethyloxycarbocyanine iodide are less effective, and 3,3'-diethylthiacyanine iodide, 1,1'-diethyl-2,2'-pyridylcarbocyanine iodide and 1,1'-diethyl-2,2'-carbocyanine iodide are only slightly effective or ineffective. 3,3'-Diethylthiadicarbocyanine iodide (250 nM) also inhibits the net K loss from intact human red cells treated with 0.1 mM Pb acetate⁹, or loaded with Ca by 2 h preincubation with inosine + iodoacetamide + CaCl₂ (refs 10, 11).

Two important conclusions should be drawn from these findings. First, these carbocyanine dyes should not be assumed to be inert probes of membrane potential, even at nanomolar concentrations. Second, and perhaps more positively, some carbocyanine dyes might prove very useful in the study of Ca-dependent K permeability systems, which seem to be widely distributed in nature^{12–14}. For example, they might be used to dissect ionic currents in voltage-clamp studies, or even as a marker during membrane purification.

I thank Dr B. Salzberg for a gift of 3,3'-dipropylthiadicarbocyanine iodide, the Director of the South London Transfusion Centre for blood, the Wellcome Trust for equipment, and Professor P. F. Baker for helpful discussions.

Intercellular junctions of frog skin epithelial cells

It has been suggested that junctional complexes between epithelial cells provide intercellular exchange of electrolytes^{1–3}, which will result in more or less coupled behaviour and functional homogeneity of neighbouring cells. In epithelia, such as frog skin, built up of several layers, electrolyte exchange through low-resistance junctions between the different cell layers would, in addition, allow participation of all layers in active transepithelial transport of ions and increase the amount of ATPase involved in transport. Na exchange between the different layers of the frog skin epithelium has recently been demonstrated in K⁺-depolarised Ouabain-poisoned skins⁴. The microelectrode experiments reported here show that low resistance connections between the different cell layers exist even under normal conditions.

Abdominal skins of *R. temporaria* and *R. esculenta* were punctured from the epithelial side perpendicular to the surface. The epithelium was properly attached to a copper grid at the corial side by a negative pressure of ~30 cm H₂O. Trans-epithelial potential difference (PD_{tr}) and short circuit current (I_{sc}) were measured using an automatic device which changed rhythmically between open circuit (o.c.) and short circuit (s.c.). During the o.c. periods, current pulses (5 μ A, 0.5 s) were applied transepithelially. The instantaneous change in PD_{tr} served to calculate the skin resistance ($R_t = \Delta PD_{tr}/I$). The microelectrodes (3 M KCl, $R = 4$ –8 M Ω , tip potential < 5 mV) were moved by a 1- μ m step motor drive (Narishige). To ensure that any structure once penetrated by the microelectrode could not be penetrated again, the microelectrode was moved only in the forward direction during the individual observation periods. The microelectrode recorded:

PD_{sc} = potential under s.c. conditions; PD_0 and PD_b = potential difference between respectively epithelial and corial side, and microelectrode under o.c. conditions ($PD_b = PD_0 + PD_{tr}$); R_0 = resistance between epithelial side and microelectrode calculated from the instantaneous change of PD_0 upon trans-epithelial injection of current. In a part of the experiments, R_0 was estimated from $(PD_{sc} - PD_0)/I_{sc}$ and R_t from PD_{tr}/I_{sc} . All electrical parameters were registered on a two-channel chart recorder. The epithelial bathing solution (Cl or SO₄ Ringer) could be exchanged in about 1 s. Na-free solution was prepared by substituting K for Na.

Impalement of two successive cell layers occurred in eight experiments by chance. Figure 1 shows the redrawn record of one observation. After penetration of dense layers, the microelectrode recorded: $PD_{sc} = -54$ mV, $PD_o = -1$ mV, $PD_b = -99$ mV and had passed 75% of R_i . Na-free epithelial perfusion produced a reversible change of PD_{sc} to -88 mV and PD_o to -44 mV, while PD_b remained essentially unchanged. Changes of R_i and R_o are quantitatively the same. According to recent investigations^{5,6} these data are typical for intracellular location of the microelectrode. Microelectrode advancement resulted in a spontaneous breakdown of the potentials to values close to those expected for the corial solution. Most likely, the microelectrode had entered an intercellular space between the epithelial cells. Part of the transepithelial resistance, however, was still in front of the microelectrode, suggesting a contribution of the intercellular spaces to R_i . The microelectrode entered an intracellular space again at 43 μ m. Potentials, resistance and response to Na-free epithelial perfusion were similar to those from the first cellular impalement. The view that a cell was punctured beneath that impalement at first and lost thereafter is supported by the fact that, in several hundred impalements of the frog skin epithelium, no cell could be repunctured. After spontaneous breakdown, a third jump to potentials of the same range as in the more outward cellular layers was observed at 52 μ m. They were stable for 20 s only, but might indicate impalement of a third cell layer before the microelectrode had passed the epithelium.

Amiloride (10^{-4} M) was used in a second impalement of the same skin to block Na entrance. The response of PD_{sc} and I_{sc} occurred without measurable delay (0.2 s) in the first and the second cell layer, also supporting the idea of electrical coupling, since alterations of the intracellular ion content would require periods of several seconds. Table 1 summarises the values of PD_{sc} , PD_o and R_o/R_i . No systematic difference exists between the two cell layers, suggesting good connection of their intracellular spaces. Although the resistance of the intercellular

junctions cannot be computed from these values (this would require impalement of several cells at given distances as performed in other epithelia^{1,3,7,8}), the order of magnitude can be estimated from a comparison of the resistances presented by the apical membrane (R_a) of the two successive layers. R_a can be calculated from

$$\frac{1}{R_i} = \frac{1}{R_a} + \frac{1}{R_a + R_b}$$

if R_b , the paracellular shunt resistance, is assumed to be measured by R_i after Amiloride (10^{-4} M) and the voltage divider ratio $PD_o/PD_b = R_a/R_b$ is used^{7,8}. The following values were obtained from the experiment, presented in Fig. 1 ($R_a = 6.8$ k Ω cm²): $R_a = 2.8$ k Ω cm² (control) and 8.0 k Ω cm² (Na free) in the first cell layer; $R_a = 3.0$ k Ω cm² (control) and 7.9 k Ω cm² (Na free) in the second layer. Appreciation of possible errors excludes the possibility that the difference in R_a , that is the resistance between the two layers, exceeds 0.3 k Ω cm². The resistance of the basolateral membranes (R_b) was considerably higher (0.9 k Ω cm² in control and 1.2 k Ω cm² with Na-free epithelial perfusion). Ion exchange between the different layers is thus less impeded than membrane passage and will provide distribution of Na through all cell layers. This must not exhibit characteristics of a single compartment since entrance across the outer border will be followed by fast distribution of Na within the cytoplasm of the first reacting cell layer, while passage into deeper layers requires penetration through—at least—space restricting junctional complexes. In addition, a certain fraction of the Na that has entered is already extruded into the intercellular spaces. This may explain why only one component during positive or negative current transients could be detected by Morel and Leblanc⁴ in transporting frog skins. But if Ouabain blocked Na extrusion

Fig. 1 Microelectrode impalement of the skin of *R. esculenta* (SO₄-Ringer) showing recording from two successive cell layers with intermediate location of the microelectrode in extracellular (corium facing) spaces. Access to intracellular spaces is labelled by solid arrows; indications of cell rupture (breakdown) are marked by asterisks. Potentials given are with respect to the epithelial bathing solution. Trans-epithelial potential (PD_{tr}) and potential difference across the outer border were recorded at the same time; PD_{sc} was recorded during short-circuiting the skin (automatically every 6 s for 6 s). The microelectrode position is given in μ m relative to the skin surface. R_i and R_o are calculated from the instantaneous changes of PD_{tr} and PD_o upon transepithelial injection (5 μ A). The skin surface was indented by the microelectrode. Thus, advancement would not be transferred into distance penetrated within the epithelium, but indicates maximal values of microelectrode movement.

larger amounts of Na exchanged across the junctional complexes and became evident as a second component.

These microelectrode observations which demonstrate that intercellular exchange of ions occurs in normal (unpoisoned and non-depolarised) frog skins are in accordance with previous suggestions from histochemical ATPase localisation⁶. The outermost reacting cell layer¹⁰ would then be the dominating location of active Na extrusion into the intercellular spaces but at least at high rates of influx, excess Na may pass into deeper cell layers to be transported out of this facultative transport pool.

Incorporation of $^{32}\text{P}_i$ into pyruvate dehydrogenase phosphate in mitochondria from control and insulin-treated adipose tissue

PYRUVATE dehydrogenase complexes (EC 1.2.4.1) isolated from mammalian sources have been shown to be inactivated by phosphorylation of the α subunit of the pyruvate decarboxylase component. This covalent modification is brought about by a tightly bound, ATP-requiring kinase, which is activated by NADH and acetyl CoA and inhibited by pyruvate, Ca^{2+} , thiamine pyrophosphate and ADP. Reactivation is catalysed by a specific phosphatase which requires both Mg^{2+} and Ca^{2+} (refs 1–6). In rat epididymal fat pads, the proportion of the complex in the active non-phosphorylated form is increased following brief exposure of pads to insulin^{6–8} and this effect persists during preparation and subsequent incubation of mitochondria with oxidisable substrates such as oxoglutarate and malate^{9,10}. The mechanism by which the interaction of insulin with the cell membrane results in the changes of this mitochondrial enzyme system has not been established. It is possible that insulin may act through activation of the phosphatase by an increase in mitochondrial Ca^{2+} concentration and this possibility has been explored extensively in this laboratory^{3,9,11}. In contrast, other workers^{7,8} have argued that the effect of insulin is brought about by an inhibition of the

kinase caused by a lowering of the mitochondrial concentration ratio ATP:ADP. We report here evidence against the latter hypothesis.

In fat pad mitochondria incubated with oxoglutarate and malate in the presence of $^{32}\text{P}_i$, we have found that the only appreciably phosphorylated protein component within the mitochondria is the α subunit of pyruvate dehydrogenase. Moreover, since the incorporation of phosphate into this subunit is slow compared with the equilibration of mitochondrial ATP with the medium $^{32}\text{P}_i$, the rate of incorporation gives an estimate of the kinase activity within the intact mitochondria. No evidence was found for any decrease in kinase activity in fat pad mitochondria from insulin-treated tissue—indeed, its activity seemed to be increased.

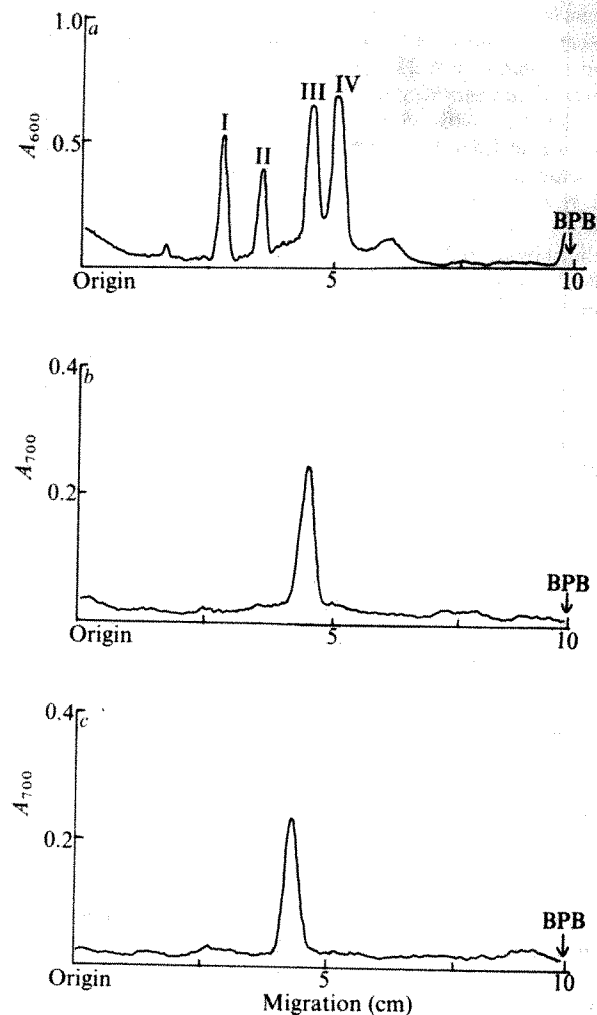

Fig. 1 SDS-polyacrylamide gel electrophoresis of components of *a, b*, pig heart ^{32}P -pyruvate dehydrogenase phosphate and *c*, of a perchloric acid precipitate of fat pad mitochondria following incubation with $^{32}\text{P}_i$ (0.2 mM and 3,000 c.p.m. μmol^{-1}) for 10 min. Samples were suspended in 50 μl of Bromophenol blue (BPB; 0.2 mg ml^{-1}), sodium dodecyl sulphate (SDS; 40 mg ml^{-1}), sucrose (0.2 g ml^{-1}), sodium phosphate (0.02 M), pH 7.0, and then incubated for 1.5 h at 60 °C. A portion (10 μl) was applied to a 7.5% (w/v) polyacrylamide gel (0.6 cm \times 10 cm) containing bisacrylamide (2.7 mg ml^{-1}), SDS (1 mg ml^{-1}) and 50 mM sodium phosphate, pH 7.0 (ref. 12). Electrophoresis was carried out at 20–25 °C for about 3 h at 8 mA per tube. After electrophoresis protein components were stained with Coomassie Brilliant Blue and the gels scanned at 600 nm (*a*). I, Dihydrolipoate transacetylase; II, dihydrolipoate dehydrogenase; III, pyruvate decarboxylase, α subunit; IV, pyruvate decarboxylase, β subunit. The ^{32}P -labelled components were located by autoradiography after the gels were washed in 7% acetic acid overnight, and the autoradiographs scanned at 700 nm (*b* and *c*). (For preparation of ^{32}P -pyruvate dehydrogenase phosphate, see ref. 3.)

Epididymal fat pads were obtained from fed male Wistar rats (180–220 g), incubated for 30 min in bicarbonate-buffered medium containing fructose (2 mg ml⁻¹) with or without insulin (10 munit ml⁻¹), and mitochondria prepared as previously described⁹. Mitochondria (about 2 mg protein ml⁻¹) were pre-incubated in air-equilibrated KCl (125 mM), EGTA (2 mM), Tris-HCl (25 mM) pH 7.4 containing 2-oxoglutarate (2 mM), malate (0.2 mM) and potassium phosphate (0.2 mM) at 30 °C for 3 min. As found previously¹⁰, the pyruvate dehydrogenase activity had by this time reached a steady-state value which remained constant for the next 10–15 min. In mitochondria from control tissue about 15% of the complex was in the active form and this was increased in mitochondria from insulin-treated tissue to about 25%. Addition of ³²P_i was made after the 3-min preincubation and incubation continued at 30 °C for varying times up to 20 min. For measurement of ³²P_i incorporation into the α subunit of pyruvate dehydrogenase, incubations were terminated by addition of perchloric acid (final concentration 2%). Insoluble proteins were precipitated by centrifugation (90 s at 10,000g in Eppendorf 3200 minifuge) and analysed by SDS-polyacrylamide electrophoresis as described in legends to Figs 1 and 2. Recovery of ³²P-labelled pig heart pyruvate dehydrogenase phosphate by this procedure was greater than 90%. For the measurement of ATP specific activity, mitochondria were separated from the ³²P_i-containing medium by centrifugation through an oil layer into a perchloric acid-glycerol mixture (see legend to Fig. 2 for details). Measurements of initial pyruvate dehydrogenase, total pyruvate dehydrogenase and glutamate dehydrogenase activities were made as described previously^{9,11} in samples of mitochondria incubated in identical conditions but without addition of ³²P-phosphate. For pyruvate dehydrogenase phosphate, a unit of enzyme activity is that amount which yields one unit of pyruvate dehydrogenase ($\mu\text{mol min}^{-1}$ at 30 °C) after complete conversion into the non-phosphorylated form with phosphatase in the presence of Mg²⁺ and Ca²⁺.

As expected, SDS-polyacrylamide electrophoresis of the proteins in fat pad mitochondria indicated the presence of a large number of different components. But after incubation of the mitochondria with ³²P_i in the presence of oxoglutarate and malate, only a single, symmetrical peak of radioactivity was separated by electrophoresis (Fig. 1c). The following evidence indicates strongly that this component is the α subunit of pyruvate dehydrogenase phosphate: (1) The *R_f* of the peak (0.45) was the same as the α subunit of purified pig heart ³²P-pyruvate dehydrogenase phosphate; little or no incorporation of ³²P was found corresponding to the other subunits of the complex (Fig. 1, a and b). Components of the pig heart complex and fat pad mitochondria have also been separated by SDS-polyacrylamide electrophoresis on adjacent tracks of a polyacrylamide slab. Incorporation of ³²P into protein components from fat pad mitochondria with *R_f* values corresponding to the β subunit (*R_f* 0.52), dihydrolipoate transacetylase (*R_f* 0.29) and dihydrolipoate dehydrogenase (*R_f* 0.36) was less than 3% of the incorporation into the peak which migrates as the α subunit (*R_f* 0.45) of pig heart pyruvate dehydrogenase. Similar results have been found using mitochondria from rat heart, liver and kidney incubated with succinate as substrate. (2) Maximum incorporation of ³²P into the peak was equivalent to 0.6–0.8 nmol phosphate per unit pyruvate dehydrogenase phosphate (Fig. 2). This level of incorporation is close to that observed with preparations of pyruvate dehydrogenase purified from pig heart³. (3) Treatment of phosphate buffer extracts of fat pad mitochondria with partially purified pig heart pyruvate dehydrogenase phosphatase¹¹ in the presence of Mg²⁺ and Ca²⁺ before precipitation of the proteins with perchloric acid resulted in complete disappearance of ³²P incorporation into the peak (*R_f* 0.45). (4) Incubation of fat pad mitochondria with pyruvate (2 mM) in the presence of oxoglutarate, malate and phosphate leads to a large decrease (by 70–80%) in the mitochondrial content of pyruvate dehydrogenase phosphate because pyruvate is a specific inhibitor of the kinase¹⁴. In these conditions, the

Fig. 2 Time courses of ³²P incorporation into the α subunit of pyruvate dehydrogenase phosphate (●, ○) and γ -³²P-ATP specific activity (■) in fat pad mitochondria incubated with ³²P_i. Mitochondria were prepared from fat pads incubated in the presence (---) or absence (—) of insulin, 10 mU ml⁻¹. After precipitation of the mitochondria in medium containing phosphate, oxoglutarate and malate for 3 min, ³²P_i was added to give 0.2 mM and a final specific activity of 1,000 to 5,000 c.p.m. pmol⁻¹ and incubation continued for various times (see text for details). After SDS-polyacrylamide electrophoresis as described in Fig. 1, the gels were cut into transverse slices (5 mm), dissolved in hydrogen peroxide (30% w/v) and then neutralised with 1 N HCl. Samples were taken up in a methoxy-ethanol-based scintillation fluid¹¹ for determination of radioactivity. In all cases a single peak of radioactivity with an *R_f* close to 0.45 was found (see Fig. 1c), incorporation into the α subunit was taken as the radioactivity in this peak with a correction (<5%) for background radioactivity taken as the mean of values in adjacent slices. Values are expressed as pmol of medium ³²P_i incorporated per munit of pyruvate dehydrogenase phosphate. Specific activity of intramitochondrial γ -³²P-ATP was measured by the method of England and Walsh¹³ modified for small concentrations of ATP (about 5 μ M). For these measurements, after incubation with ³²P_i for varying times, the mitochondria were centrifuged through an oil layer (silicone oil MSS60: dinonyl phthalate (3:2)) into perchloric acid (3%) containing glycerol (25% w/v). Each value is the mean \pm s.e.m. of observations made on three to eight separate mitochondrial preparations.

maximum incorporation of ³²P_i into the peak (*R_f* 0.45) was decreased in three separate preparations of mitochondria by a very similar percentage. Closely parallel decreases in ³²P_i incorporation and pyruvate dehydrogenase phosphate content were also apparent on incubating mitochondria in the presence of uncoupler (FCCP, 1 μ M).

The incorporation of ³²P_i into the α subunit took 10–15 min to reach completion in mitochondria from control tissues. In mitochondria from insulin-treated tissue, incorporation seemed complete by 5 min (Fig. 2). The maximum incorporation (0.6–0.8 nmol phosphate per unit pyruvate dehydrogenase phosphate) was not significantly affected by insulin treatment. The specific activity of mitochondrial ATP was found to rise to that of the medium phosphate within 30 s (Fig. 2). Consequently the rate of incorporation of ³²P_i into the α subunit gives an estimate of the rate of the kinase reaction within the mitochondria, using the present conditions where no changes in the phosphorylation state of pyruvate dehydrogenase complex are occurring. The rate was found to be significantly greater in mitochondria from insulin-treated tissues. The increase in incorporation after 5 min was $44 \pm 11\%$ if results were expressed in terms of total pyruvate dehydrogenase activity and $36 \pm 9\%$ if expressed in terms of mitochondrial glutamate dehydrogenase (mean \pm s.e.m. for seven separate paired preparations of mitochondria). In two experiments, measurements were also made after incubation for 2 min and again increases of incorporation (by 17 and 29%) were observed.

These results provide strong evidence against the hypothesis^{7,8} that the increase in the non-phosphorylated form of pyruvate dehydrogenase in adipose tissue exposed to insulin is brought

about by a decrease in kinase activity. Moreover, measurements of some of the known effectors of the kinase (ATP, ADP, NAD, NADH, acetyl CoA, CoA) have been made in mitochondria from control and insulin-treated tissue (refs 10, 15 and unpublished work with B. J. Bridges), but no clear evidence has been found for any changes which could result in a decrease in kinase activity. In particular, no reduction in the ATP:ADP concentration ratio has been observed. We conclude that it is more likely that the effect of insulin is mediated through an increase in the activity of the phosphatase. The subsequent increase in the active non-phosphorylated form of pyruvate dehydrogenase may then result in the enhanced rate of phosphorylation observed in the present studies. Since no differences in the activity of pyruvate dehydrogenase phosphatase persist in extracts of mitochondria from control and insulin-treated tissue¹⁶, insulin may act through changes in the mitochondrial concentration of one or more effectors of the phosphatase.

The only two effectors of the phosphatase that have been recognised to date are Mg^{2+} and Ca^{2+} which both activate the enzyme^{1,3,6} and so the strong possibility remains that the effects of insulin may be brought about by an increase in the free concentration within adipose tissue mitochondria of one or both of these divalent metal ions.

This work was supported by a grant from the MRC. We are grateful to Dr P. J. England and Professor P. J. Randle for advice and discussion.

Circular and elongated linear forms of measles virus nucleocapsid

PARAMYXOVIRUSES are assuming increasing importance as possible causative agents of several human diseases^{1,2}. To date little is known about their mode of replication, although it has been suggested that the nucleocapsid replicates without extensive dissociation of the protein from the nucleic acid component³. Previous reports on the structure of nucleocapsids extracted from virions or infected cells, with or without further purification, have shown by electron microscopy that the molecules are linear, and although short pieces can be found, the majority are about 1.0 μ m long⁴. We report here the occurrence of rare circular forms of measles nucleocapsid as well as linear molecules of greater than normal length.

Three strains of measles virus have been examined; a non-haemagglutinating strain⁵ (P9), a haemagglutinating strain (TC243) and measles virus isolated during a transfection experiment using DNA extracted from the brain of a multiple sclerosis patient (H.V.T. and Haire, unpublished). The origin of this virus (provisionally designated Miller virus), has not yet been established. The viruses were

grown in human embryonic lung (HeLu) and Vero cell monolayers which were infected with virus (about 1 plaque-forming unit per cell) by adsorption for 1 h at 37 °C and cultured in 199 medium + 10% calf serum at 37 °C for various times. Material for electron microscopy was prepared, with equivalent results, by lysing monolayers with 2% phosphotungstic acid or by rubbing off cells into the

Fig. 1 Circular nucleocapsids of different sizes: a, b, and c, Miller virus grown in HeLu cells 1.5, 1.1 and 0.5 μ m respectively; d, TC243 virus grown in HeLu cells, 0.6 μ m; e, P9 virus grown in Vero cells, 0.5 μ m. $\times 125,000$.

Fig. 2 Linear nucleocapsids of different lengths: *a*, Miller virus grown in HeLu cells, 1.2 μm ; *b*, P9 virus grown in HeLu cells, 3.6 μm . $\times 60,000$.

medium followed by centrifugation at 30,000 r.p.m. for 1 h with resuspension of the pellet in phosphate-buffered saline (PBS), or by washing monolayers with distilled water followed by Dounce homogenisation and low speed centrifugation to remove debris. The preparations, without further purification, were put on to carbon-Formvar coated grids, excess solution was removed with filter paper and, in the latter two methods, grids were then stained with 2% phosphotungstic acid. Grids were examined immediately in an AEI Corinth 500 electron microscope.

Unbroken circular nucleocapsids were found in all three virus strains and both cell cultures (Fig. 1), but were rare compared to the linear forms. The size of the circles varied between 0.2 and 1.5 μm and could be found in preparations from cultures from 18 h post-infection onwards, that is, at the normal time of nucleocapsid accumulation⁶. Present techniques do not indicate whether the number of circles varies during the growth cycle of the virus. In addition to unbroken molecules a small proportion of molecules showing one or more breaks or discontinuities were observed. It is not possible to ascertain whether these breaks are real or artefacts of preparation. No rings or linear molecules were found in uninfected cultures.

The most frequently found length of linear nucleocapsid was about 1.1 μm (Fig. 2*a*), but we also observed abnormally long nucleocapsids (Fig. 2*b*) in all three virus strains with one of nine times this length in Miller virus grown in HeLu cells. Long molecules seem to increase in number and length with time after infection, particularly in HeLu cells in which the cytopathic effect is less destructive

permitting observation for times up to 3 weeks post-infection. Although no circular molecules have been described previously for any paramyxovirus, rare nucleocapsid molecules of 2 and 4 μm lengths which were considered to be end-to-end aggregates of normal length nucleocapsids have been reported for the parainfluenza virus SV5 (ref. 2).

Our results do not allow any conclusions as to the origin and function of either the circular or the long molecules, but they may indicate, assuming that the molecules contain RNA, that there are circularisation processes for RNA; evidence for this has recently been presented in an oncornavirus system⁷. Since no ligase for RNA is known, we speculate that circles arise from the presence of complementary ends on some or all of the RNA molecules. The long molecules could result from end-to-end linkage of similar RNA molecules.

Although it cannot be ruled out that the circles are accidental forms of nucleocapsid with no role in the normal replication process, nevertheless, we suggest two possible functions for these molecules. First, that the circles represent the templates from a replicative intermediate arising during a "rolling circle" type of replication. Such a model could also provide an alternative explanation for the presence of long molecules. The varying size of the circles could be accounted for by the presence of replicating defective genomes. Second, the circles are encapsidated RNA molecules which function as templates for DNA replication (presumably by a reverse transcriptase) ultimately producing circular double-stranded DNA molecules which could be in suitable form for integration into the cell genome. This would provide a mechanism to explain the existence of infectious DNA molecules which have been obtained from cultures persistently infected with measles⁸. There may be a relationship between such a mechanism and the integration of virus-specific sequences which has been suggested to occur in diseases such as systemic lupus erythematosus and multiple sclerosis⁹.

It will be interesting to see whether similar forms of nucleocapsid can be identified in other RNA virus systems.

This work was supported by an MRC Programme grant. We thank Mr G. Clarke and Mr T. McLaughlin for assistance.

RNA homology between subacute sclerosing panencephalitis and measles viruses

VIROLOGICAL and immunological studies in subacute sclerosing panencephalitis (SSPE) have associated this disease with measles virus^{1,2}. Measles-like virus (referred to as SSPE virus) has been isolated from brain material of patients with SSPE and all SSPE patients reveal an hyperimmune reaction to measles virus antigen. In spite of these major findings the aetiology and pathogenicity of SSPE is still not understood, and the rarity and rural prevalence of this disease

remain unexplained³. If measles virus is involved then additional factors either host or virus dependent, must determine the disease since the occurrence of measles virus and its acute infection cannot be correlated with SSPE. So far, no major host factor, either immunological or genetic, has been discovered which would answer these questions⁴.

Biological and ultrastructural comparisons of SSPE and measles viruses have indicated some differences⁵⁻⁷. The present communication compares several SSPE isolates with measles virus in terms of genome homology. The genome of measles and SSPE viruses consists of a single-stranded piece of RNA which has a sedimentation coefficient of 50S (refs 8 and 9). After infection this RNA is transcribed into complementary messenger (m)RNA molecules which sediment at approximately 18S in sucrose gradients. The genome homology of different viruses can be compared simply by hybridising either the mRNAs of different viruses to one radioactive labelled genome or vice versa. One problem with hybridisation experiments involving SSPE viruses is that in the early passage levels after isolation, large amounts of defective genomes are produced. These RNAs contain some of the sequences of the infectious genome and have the same sedimentation coefficients as the virus messengers^{10,11}. Thus, if "18S" RNAs from infected cells are used in hybridisation experiments they will "self-hybridise". Such a background of self-hybridisation would give erroneous results in any hybridisation experiments. The mRNAs were therefore purified on the basis of their poly(A) content by chromatography on oligo d(T)-cellulose. A second problem is the difficulty in producing a complete set of highly labelled mRNAs or genome RNAs because of the long and variable growth rates of these viruses. Therefore we have used a competition-hybridisation method where only one or two RNAs need to be labelled and the different growth rates are unimportant.

The viruses compared in the present study were two measles viruses (the attenuated Edmonston strain and Woodfolk, a wild measles strain), three strains of SSPE (Mantooth, Lec and Jac), the immunologically related Onderstepoort strain of canine distemper virus (CDV) and a bovine-meningo encephalitis virus (107 virus). The latter virus has been isolated from the brain of a calf which had died from a meningo-encephalomyelitis, and on the basis of its morphological and biological characteristics belongs to the measles-CDV-Rinderpest virus group¹². The RNA of parainfluenza 1 6/94 virus and Vero cell ribosomal RNA were used as controls.

All viruses were grown in Vero cells except 107 virus which was cell associated with BHK cells, and mRNAs were isolated between 18 and 60 h after infection. In the competition hybridisation experiments we selected two viruses: the Edmonston and Mantooth strains as proto-types of measles and SSPE respectively. Unlabelled genome RNA was prepared from purified nucleocapsids as previously described⁹. The corresponding mRNAs of these two viruses were labelled with ³H-uridine by adding large quantities (100 μ Ci ml⁻¹) of isotope to actinomycin D-treated infected cells. The mRNAs were extracted and purified by sucrose-gradient sedimentation and oligo d(T)-cellulose chromatography (Fig. 1). Unlabelled mRNAs of all the viruses were then purified from infected cells using the same method. The genetic relatedness or comparative homology of the viruses could be measured by the ability of the unlabelled or "cold" mRNAs to compete with the hybridisation of the labelled mRNA to its corresponding genome.

A typical set of results obtained is shown in Figs 2 and 3. Figure 2 shows the competition profiles of the mRNAs against the hybridisation of ³H-labelled Edmonston mRNA to its genome. It can be seen that the Woodfolk strain of measles virus shares 100% homology with the Edmonston. Similarly, the three SSPE viruses tested shared 100% homology with Edmonston measles. CDV and 107 virus shared

Fig. 1 Purification of virus-specific mRNAs. RNA was extracted from infected cells by the following procedure. Cells were washed twice with ice-cold NTE buffer (0.01 M Tris-HCl (pH 7.5), 0.1 M NaCl, 0.001 M EDTA), scraped into fresh NTE buffer and collected by centrifugation at 2,000g for 10 min at 4 °C. Pellets were resuspended in sterilised distilled water (0.1 ml) and allowed to swell on ice for 15 min. Cells were disrupted by douncing 10 strokes in a tight-fitting glass homogeniser, and nuclei were removed by centrifugation at 800g for 8 min. Supernatants were removed, made 2% in sodium dodecyl sulphate (SDS) and heated at 56 °C for 2 min. Released RNA was directly sedimented on 35 ml linear 15 to 30% (w/w) sucrose gradients in NTE buffer containing 0.5% (w/v) SDS. Gradients were centrifuged for 16 h at 20,000g at 20 °C. After centrifugation, fractions were collected from the bottom of the tube using an LKB pump and an ISCO fractionator which measured absorbance continuously at 254 nm. Aliquots (25 μ l) of each fraction were precipitated with 3 volumes of 10% (w/v) trichloroacetic acid (TCA). Precipitates were collected using a Millipore Manifold 3025 filtration apparatus, and radioactivity was counted in Bray's solution. A typical radioactivity profile for Edmonston-measles virus is shown in *a*. RNA which sedimented at 12 to 36S (fractions 25-14) was pooled and precipitated overnight in 2 volumes of ethanol at -20 °C. Precipitates were collected by centrifugation at 8,000g for 30 min and allowed to dry at room temperature for 20 min. Samples were dissolved in TE buffer (0.01 M Tris-HCl (pH 7.4), 1.5 M LiCl, 0.001 M EDTA), allowed to stand at 4 °C for 24 h and then centrifuged at 12,000g for 25 min. The pellets which contained double-stranded RNA intermediates were discarded and the supernatants (predominantly single-stranded RNA) were precipitated in 2 volumes of ethanol as described above. Precipitates were collected, dissolved in 0.01 M Tris-HCl (pH 7.5), 0.5 M NaCl, 0.001 M EDTA containing 0.1% (w/v) SDS (binding buffer) and applied to 0.4 g of oligo d(T)-cellulose in a disposable pipette column. The column was washed with 8 ml of binding buffer and bound RNA was eluted with 0.005 M Tris-HCl (pH 7.4), 0.001 M EDTA containing 0.1% (w/v) SDS. Radioactivity levels were determined (Fig. 1*b*) and the purified mRNA precipitated with ethanol. The arrows in *a* represent the sedimentation position of Vero cell 28S and 18S ribosomal RNA; in *b* the arrow indicates the change of buffer from binding to elution.

Fig. 2 Competition of unlabelled mRNAs on the hybridisation of Edmonston virus genome to its mRNA. Samples of Edmonston 50S RNA, ^3H -uridine labelled (12,000–14,000 c.p.m.) Edmonston mRNA and various amounts of unlabelled mRNAs were mixed in $2\times\text{SSC}$ ($\text{SSC} = 0.15\text{ M}$ sodium citrate, 0.15 M NaCl) containing 0.05% (w/v) SDS. Mixtures (final vol. $150\text{ }\mu\text{l}$) were added to glass tubes ($0.2\times 6.0\text{ cm}$). The tubes were briefly centrifuged to allow complete mixing of the RNAs and then sealed. After denaturation by boiling for 4 min hybridisation was allowed to occur by incubation at 60°C for 12–14 h. Tubes were cooled on ice, opened and the contents treated with ribonucleases (pancreatic $50\text{ }\mu\text{g ml}^{-1}$, T_1 $8\text{ }\mu\text{g ml}^{-1}$) at 37°C for 30 min. The reaction was stopped by the addition of 3 volumes of 10% (w/v) TCA and acid-insoluble radioactivity determined.

30% homology with measles virus, whereas parainfluenza 1 6/94 virus mRNA and Vero cell ribosomal RNA provided only a low and inconsistent level of competition. Figure 3 shows an identical experiment where the viruses were compared with the Mantooth strain of SSPE virus. It can be seen that all three strains of SSPE virus share 100% homology. However, in sharp contrast to the previous data the two measles virus strains were able only to compete out approximately 90% of the labelled SSPE mRNAs. It would therefore appear that, whereas all the genetic information contained in the measles genome is present in SSPE virus, the latter contains an additional piece of genetic information. CDV and 107 virus shared 38% homology with Mantooth SSPE, an increase in genetic relatedness to that observed with Edmonston measles virus. The parainfluenza 1 6/94 and Vero cell RNAs showed again only a low and inconsistent degree of relatedness. A summary of the percentage homologies of the different viruses to the measles and SSPE prototypes is shown in Table 1.

Table 1 Summary of competition-hybridisation results*

To:	% Similarity of	
	Edmonston	Mantooth
Edmonston	100	91
Woodfolk	97	88
Mantooth	99	100
Lec	98	102
Jac	99	99
CDV	29	43
107 Virus	28	41
6/94	19	18
Vero cell RNA	16	12

*The values represent the means of three individual experiments.

These results show that, whereas all the genetic information of measles virus is contained in SSPE viruses, the latter apparently contain an additional 10% information.

These results are in disagreement with the direct hybridisation experiments of Yeh⁸ who reported that the Woodfolk strain of measles virus contained only 60% of the genetic information of the SSPE-Lec virus genome. But in this work purified mRNAs were not used, saturation levels of annealing were not obtained, and the genetic relationship of the SSPE to the measles genome was not described.

An intriguing explanation for the results obtained would be that the viruses of SSPE may arise as a recombination

Fig. 3 Competition of unlabelled mRNAs to the hybridisation of Mantooth virus genome to its mRNA. Details were as described in Fig. 2. Each sample contained 16,000 c.p.m. of ^3H -uridine-labelled Mantooth mRNA.

of measles virus with another as yet unknown second virus. The additional information represents a molecular weight in the order of $4-5 \times 10^5$ which would have a sedimentation of about 12S. Defective RNAs of this size have been reported for paramyxoviruses including measles^{11,14}. Therefore it would seem likely that if a recombination occurs then it is with the intact genome of measles virus and a defective genome of the second virus.

The data exclude the possibility that the genomes of the SSPE viruses tested in the present study have arisen from a recombination between a complete and defective measles RNA genome, since the mRNA corresponding to the additional genomic information of SSPE is not present in measles-infected cells. The formation of covalently linked recombinant genomes is neither genetically nor biologically impossible. Recent work with vesicular stomatitis virus (VSV) has shown that mixed infections with defective and infectious viruses can result in the production of genetically stable recombinant genomes¹⁴ and a state of virus persistence *in vitro*¹⁵. A similar mechanism of mixed infection would account for the slow process of infection and the accompanying persistence observed in SSPE.

If such a double infection/recombination does occur in SSPE, it would account for two important features of the disease. Firstly, the rarity of the disease would be consistent with the low possibility of a mixed infection resulting in genetic recombination. Secondly, if the second virus is an animal RNA virus then it would account for the predominant rural distribution of the disease.

Interferon-mediated protein kinase and low-molecular-weight inhibitor of protein synthesis

PROTEIN synthesis in cell-free systems from mouse L-cells pretreated with the antiviral agent interferon¹ shows an enhanced sensitivity to inhibition by double-stranded RNA (dsRNA)^{2,3}. The possible significance of this with respect to events in intact interferon-treated virus-infected cells has already been discussed^{2,4}. We have already shown that

the addition of small amounts of a post-ribosomal supernatant fraction from interferon-treated cells (interferon cell sap) renders protein synthesis in control cell-free systems sensitive to inhibition by dsRNA⁴. Our results are in accord with a two-step model involving an initial 100-fold activation of an inhibitor on incubation of the interferon cell sap with ATP and dsRNA (activation step), the activated inhibitor then interacting with the protein-synthetic system to inhibit translation (inhibitory step)⁵. In view of the dependence of the inhibition of protein synthesis upon incubation with ATP as well as dsRNA⁵ it was of interest to determine if a protein kinase(s) is involved, as seems to be the case in reticulocyte lysates in which phosphorylation of the initiator Met-tRNA binding factor (IF-E2) has been implicated following incubation of the lysates under a variety of inhibitory conditions including the presence of dsRNA (P. Farrell,

Fig. 1 A dsRNA-dependent protein kinase activity in cell sap from interferon-treated cells: electrophoretic analysis of phosphorylated polypeptides. Control cell sap minus (1) and plus (2) dsRNA. Interferon cell sap minus (3) and plus (4) dsRNA. Each cell sap (10 μ l) was incubated with 0.1 mM γ -³²P-ATP (8 Ci mmol⁻¹, Radiochemical Centre) plus or minus *Penicillium chrysogenum* phage dsRNA⁷ (400 ng ml⁻¹) in a final volume of 13 μ l. Incubation was for 40 min at 30 °C. Material equivalent to 5 μ l of each incubation was analysed by electrophoresis on a 10% polyacrylamide slab gel containing 0.1% sodium dodecyl sulphate (SDS)^{8,9}. An autoradiograph of the stained, dried gel is shown. The numbers to the left give the molecular weights in thousands of the major reovirus polypeptides λ 1, λ 2, μ 2 and σ 3¹⁰, included as markers. Interferon treatment of mouse L-cells with low doses (5 to 20 effective units ml⁻¹) of highly purified mouse interferon ($\geq 5 \times 10^7$ reference units mg⁻¹ protein) and the preparation of cell extracts and of the dialysed interferon and control cell saps were as described previously^{2,4}.

K. Balkow, T. Hunt and R. J. Jackson, personal communication⁶. In accord with this, we report here the presence of a dsRNA-dependent protein kinase activity in interferon cell sap. The inhibitor of protein synthesis which is activated on incubation of interferon cell sap with ATP

Fig. 2 Phosphorylation of histones by a dsRNA-dependent protein kinase in cell sap from interferon-treated cells: electrophoretic analysis of the phosphorylated histones. Control and interferon cell saps were first activated as in Fig. 1 but with unlabelled ATP (1 mM). Histone was then labelled by subsequent incubation of either the control cell sap (2 μ l) activated minus (1) or plus (2) dsRNA, or the interferon cell sap (2 μ l) activated minus (3) or plus (4) dsRNA, with 0.12 mM γ -³²P-ATP (8 Ci mmol⁻¹) and 1 μ l of 2 mg ml⁻¹ calf thymus histone (type IIA, Sigma). Incubation was for 30 min at 30 °C in a total volume of 5 μ l. Material equivalent to one fourth of each incubation was analysed by electrophoresis as in Fig. 1. An autoradiograph of the stained, dried gel is shown. The molecular weight markers were as in Fig. 1.

and dsRNA, however, is heat stable and of relatively low molecular weight. It does not correspond either to the major polypeptide product of the interferon-dsRNA specific phosphorylation, or, presumably, to phosphorylated IF-E2.

To determine whether a protein kinase might be involved in the activation of the inhibitor formed in response to incubation of the interferon cell sap with dsRNA and ATP⁵, the incubation was carried out in the presence of γ -³²P-ATP and the phosphorylated polypeptides were analysed by electrophoresis on polyacrylamide gels (Fig. 1). With interferon cell sap plus dsRNA (Fig. 1, channel 4) a major phosphorylated band (X) with an apparent molecular weight of about 60,000 (60K) and an additional band (Z), which migrated near the ion front, were observed which were not detected in corresponding controls. The phosphorylated polypeptide Y of approximately 30,000 (30K) in molecular weight was enhanced in the presence of dsRNA in both interferon and control preparations, but the increase was routinely greater in the interferon than the control (Fig. 1, channels 2 and 4).

Fig. 3 Gel filtration chromatography of the activated inhibitor. Control and interferon cell saps were activated as in Fig. 1 but in the presence of unlabelled ATP (1 mM), heated to 90 °C for 5 min and centrifuged at 10,000 g for 10 min to remove denatured protein. Each supernatant (25 μ l) was fractionated by passage through a column (3 mm in diameter and 130 mm long) of Sephadex G-25 (Fine) equilibrated and eluted with 50 mM KCl and 20 mM Tris-hydrochloride (pH 7.6). Fractions (50 μ l) were collected and 2 μ l samples assayed for inhibitor activity on the translation of encephalomyocarditis virus (EMC) RNA in cell-free systems (25 μ l final volume) from control mouse L-cells^{4,5,9}. The left hand ordinate gives the incorporation (c.p.m. per 10 μ l sample) of a ¹⁴C-amino acid mixture into hot trichloroacetic acid-insoluble polypeptide in response to EMC RNA in the cell-free system^{4,5,9}. Interferon (△) and control (□) cell saps each activated in the presence of dsRNA. Interferon and control cell saps activated in the absence of dsRNA gave results essentially identical to the control plus dsRNA (□). The right hand ordinates give the protein concentration¹² (○) and absorbance at 260 nm (●) of the fractions obtained with the interferon cell sap which had been activated in the presence of dsRNA. The peak of optical density at 260 nm eluting between 0.8 and 1.1 ml represents primarily the ATP added for activation.

Fig. 4 *a*, Absence of phosphorylated polypeptides X and Y (Fig. 1) in the heat-stable inhibitor fraction. Interferon and control cell saps were incubated with γ - 32 P-ATP and dsRNA as in Fig. 1. A portion of each was heated to 90 °C for 5 min and centrifuged at 10,000g for 10 min. Samples (2 μ l) of the supernatant and of the original (unheated) activated material were analysed by electrophoresis on a polyacrylamide slab gel as in Fig. 1. Activated control cell sap (1) and supernatant after heating (2). Activated interferon cell sap (3) and supernatant after heating (4). *b*, Assay for protein kinase activity with activated inhibitor in the presence of histone, cell sap (S100), or post-mitochondrial supernatant (S10) fractions. Control and interferon cell saps were activated in the presence of dsRNA as in Fig. 1 but with unlabelled ATP (1 mM), heated to 90 °C for 5 min and centrifuged at 10,000g for 10 min. Samples (2 μ l) of each supernatant (interferon and control) were then incubated with γ - 32 P-ATP (2 μ l, 5 μ Ci μ l $^{-1}$, 8 Ci mmol $^{-1}$) in the presence of: (9 and 10) histone alone (1 μ l, 2 mg ml $^{-1}$ as in Fig. 2); (5 and 7) control cell sap alone (3 μ l); (6 and 8) control cell sap (3 μ l) plus histone (1 μ l); (11 and 12) interferon cell sap alone (3 μ l); (13 and 14) a post-mitochondrial supernatant (S10) fraction (3 μ l) from mouse L-cells which had been preincubated and dialysed in preparation for its use in the cell-free system 1,9 . Incubations for channels 7, 8, 10, 12 and 14 were with the supernatants from heated activated interferon cell sap, those for channels 5, 6, 9, 11 and 13 were with corresponding control material. Incubations were for 30 min at 30 °C. Samples representing one fourth of each incubation were analysed by electrophoresis on polyacrylamide slab gels 8,9 . Autoradiographs of the stained, dried gels are presented. The molecular weight markers were as in Fig. 1.

The appearance of these phosphorylated bands (Fig. 1, X, Y and Z) could reflect the presence of a new or increased kinase(s) or of new substrates (or both). As a test for an enhanced protein kinase activity, a potential substrate (calf thymus histone) was added to the interferon and control cell saps after activation and its phosphorylation examined by gel electrophoresis (Fig. 2). The marked increase, in the presence of interferon cell sap and dsRNA, in the phosphorylation of one of the major histone bands in particular (Fig. 2, channel 4) strongly suggests the activation of a specific kinase, although by no means excluding an additional or altered substrate as part of the explanation.

The major product of the interferon-dsRNA mediated kinase activity (X, Fig. 1) does not, however, appear to correspond to the inhibitor of protein synthesis activated on incubation of the interferon cell sap with ATP and dsRNA. This activated inhibitor is heat stable and seems to be of relatively low molecular weight. Thus after activation of the inhibitor by incubation of the interferon cell sap with dsRNA and ATP, heating to 90 °C for 5 to 15 min and centrifugation to remove the heat-denatured protein, the activated inhibitor is recovered *in toto* in the supernatant fraction. On passage of this supernatant through a column of Sephadex G-25 the inhibitor is retained separate from the peak of residual protein excluded from the column (Fig. 3). It seems unlikely,

therefore, that the activated inhibitor corresponds to either X or Y (Fig. 1). In fact, neither of these remain in the active supernatant on centrifugation after heating to 90 °C as above (Fig. 4, channels 1-4). (They can be recovered from the pellet, data not shown.)

Accepting that the activated inhibitor is neither X nor Y (Fig. 1), it was of interest to ask if a protein kinase is involved in the action of the activated inhibitor (inhibitory step). The heated activated inhibitor has no detectable kinase activity when assayed with histone as a substrate in the absence of added cell sap (Fig. 4, channels 9 and 10). Nor does it seem to function as an activator of protein kinase activity in cell sap or in the complete protein-synthetic system (Fig. 4, channels 5-8 and 11-14), although in the latter case a small quantitative difference in the 60K and 30K regions of the gel cannot be excluded (Fig. 4, channels 13 and 14). The differences in intensity of band Z here and in Fig. 1 are intriguing but variable and their significance is not yet clear.

There is, therefore, in cell sap from interferon-treated cells a dsRNA-dependent protein kinase(s) absent (or very much reduced) in corresponding controls. The main high-molecular-weight phosphorylated polypeptide products of this kinase(s) (X and Y, Fig. 1) do not, however, correspond to the heat-stable, low-molecular-weight inhibitor formed in response to incubation of interferon cell sap with ATP and dsRNA. Nor does the inhibition mediated by this

inhibitor seem to involve phosphorylation of these polypeptides. On the other hand, on a molecular weight basis alone, it is possible that a component of the band Z (Fig. 1) might be the active inhibitor, although our initial attempts to establish this have proved inconclusive. Certainly, until the biochemical nature of Z and of the activated inhibitor is known, the details of the activation and inhibitory steps worked out and the basis of the requirement for ATP understood, it would be premature to exclude a possible role for a protein kinase(s) in the inhibition of protein synthesis in these systems.

In more general terms, modulation of protein kinase activity by interferon may be of wider significance and the phosphorylation of histone (Fig. 2) could be of interest in this respect. It is conceivable that such kinases could be involved in the control of transcription or of other viral or cellular functions¹³ and thus account, in part at least, for the diversity of effects attributed to interferon.

This investigation was aided by a grant from the American Cancer Society to W.K.R. M.J.C. was the recipient of a Mr and Mrs John Jaffe (Royal Society) Fellowship. An interferon-dsRNA specific protein kinase activity has also recently been observed by P. Lengyel and M. Revel and their colleagues^{14,15}.

Primary and secondary variants in immunoglobulin heavy chain production

WE have isolated numerous variants of a mouse myeloma cell line which synthesised altered heavy immunoglobulin chains and normal light chains after treating the line with the acridine mustard ICR-191 (refs 1-4). The four types of primary variants that we found are shown in Table 1. The primary variant clones were generally stable but we did find one clone which on recloning produced subclones synthesising a variant heavy chain with molecular weight lower than that synthesised by the primary clone. This observation raised the question of whether certain primary variants might have a built-in instability and that the original mutation might be affecting a regulatory process. We were thus led to seek additional examples of spontaneous secondary variant production to see if this were a more general phenomenon. Here we report our results.

In the earlier experiments we isolated many independent

clones which fell into the four primary variant types. Two types synthesised heavy chains which are shorter than the parent and which lack the parental subclass serotype; two types synthesise heavy chains of a different subclass serotype from the parent. We also characterised the variants by the manner in which they assemble their heavy and light chains and by peptide analysis¹⁻⁴. Occasionally a primary variant clone showed decreased heavy chain synthesis while continuing to make the altered heavy chain. To retrieve those cells continuing to make the altered heavy chain, we recloned the primary variant cells. As expected, most subclones were of either the primary variant heavy chain type or the light chain producer type. The exception was the variant mentioned above synthesising a heavy chain of molecular weight 50,000: on recloning it we found, in addition to clones synthesising heavy chains of molecular weight 50,000 and clones that had lost the variant heavy chain synthesis completely, numerous subclones synthesising a variant heavy chain of molecular weight 40,000 (ref. 3).

In the present experiments the parental cell lines 45.6, 45.6.2.4 and 45.6.3.2 were derived from the MPC 11 tumour which synthesises an IgG-2b immunoglobulin⁵. The original variants were isolated from the parental population after mutagenesis with ICR-191^{3,4}. Mutagenised cells were cloned in soft agar and overlaid with an antiserum directed against either the completely reduced and alkylated MPC 11 (γ 2b) heavy chain or the Fc region (C-terminal half of the MPC 11 heavy chain). An antibody-antigen precipitate developed over those clones synthesising and secreting parental heavy chains. "Unstained" variant clones were retrieved from the agar and grown to mass culture. Unstained clones included clones which had ceased heavy chain synthesis completely, clones which continued heavy chain synthesis but had difficulty in secreting the heavy chain, and clones which synthesised an altered heavy chain not recognised by the overlay antiserum. The details of cell culture and cloning and the analysis of variant clones have been described previously^{3,4}.

To select secondary variants from individual primary variants synthesising altered heavy chains, we followed the same cloning-antibody overlay procedure without subjecting the cells to any additional mutagenesis. In this type of selection, the primary variant clones were "unstained" (as originally selected). "Stained" clones included those clones which secreted the primary variant heavy chain in sufficient quantity to yield a visible precipitate and those clones which synthesised and secreted a new immunoglobulin heavy chain which was recognised by the overlay antiserum. The same protocol would have selected clones synthesising and secreting the parental MPC 11 immunoglobulin, that is, revertants. To date, in several independent experiments, we have found no revertants.

Secondary variants have however been found in several experiments. In one study, a primary variant (45.6.3.2 ICR 11.19)^{3,6} which synthesised a heavy chain of molecular weight 50,000, was recloned and overlaid with an antiserum directed against the completely reduced and alkylated heavy chain of the MPC 11 immunoglobulin (IgG-2b). The primary variant had been selected originally as "unstained" by this same method. When the variant was recloned, sixteen of 478 clones were now found to be stained. Seven of these sixteen clones were grown to mass culture and analysed by Ouchterlony analysis of cytoplasmic contents and secreted immunoglobulin, and by electrophoresis of radiolabelled immunoglobulin on acrylamide gels containing sodium dodecyl sulphate. Five of the seven were identical to the primary variant (45.6.3.2 ICR 11.19) in that they synthesised heavy chains of molecular weight 50,000 which assembled with light chains to yield HL, L2 and L components. Now, however, they secreted the variant heavy chain in sufficient quantity to be detected as stained in the overlay procedure. The remaining two clones were found to synthesise heavy

§Anti- $\gamma 2a$ = rabbit anti-LPC1 (IgG-2a κ).

chains of increased (normal) size (molecular weight 55,000), which bore the $\gamma 2a$ serotype. Figure 1 shows the result of this experiment. This result is contrasted to the earlier experiment in which another independent clone of the same primary type 45.6 ICR 4.68 (ref. 3) gave rise, on recloning, to clones synthesising heavy chains of molecular weight 40,000. These experiments are summarised in Table 2.

In the second series of experiments, the single primary variant which had been previously characterised and shown to synthesise a $\gamma 2a$ heavy chain of molecular weight 75,000 (45.6.2.4 ICR 9) was recloned and overlaid with an antiserum directed against the Fc region of MPC 11 ($\gamma 2b$) or with an antiserum directed against a $\gamma 2a$ immunoglobulin (LPC-1). Neither antiserum is specific for subclass determinants. Each is reactive with both $\gamma 2a$ and $\gamma 2b$ myeloma proteins. In the initial experiment, one of 660 clones was stained with the anti-MPC 11 Fc serum. This clone was found to be synthesising and secreting heavy chains which continued to bear the $\gamma 2a$ serotype, but were now of decreased (normal) size (molecular weight 55,000). The results are shown in Fig. 1.

In a subsequent experiment with 45.6.2.4 ICR 9, one of 766 clones was stained with the anti- $\gamma 2a$ antiserum. This stained clone continued to synthesise the primary variant heavy chain of molecular weight 75,000. Upon recloning this stained clone, 994 out of 995 clones were unstained, indicating a considerable degree of clonal variability. One of the 995 clones was stained and was now found to be making a $\gamma 2a$ chain of molecular weight 55,000.

In another independent experiment utilising anti- $\gamma 2a$ antiserum, five out of 1,150 clones were stained. Four of the five were identical to the primary variant except that they now secreted the variant heavy chain in sufficient quantity to be detected as stained in the overlay procedure. The remaining clone synthesised a heavy chain of decreased (normal) size (molecular weight 55,000) having the $\gamma 2a$ serotype. This secondary variant was quite stable, since on recloning, all of 3,000 subclones were stained with the anti- $\gamma 2a$ antiserum and 15 subclones examined by radiolabelling and electrophoresis on acrylamide gels were identical in the size and assembly patterns of the heavy and light chains they synthesised.

The primary variants which gave rise to secondary variants have certain features in common. Neither the molecular weight 50,000 heavy chain nor the molecular weight 75,000 heavy chain is assembled well into H_2L_2 and

neither is secreted well from the cell. The assembly patterns of these primary variants are shown in Fig. 1. Note the relative lack of H_2L_2 in panels *a1* and *b1* as compared with the relative abundance of H_2L_2 in panels *a2* and *b2*. The

Fig. 1 Comparison by electrophoresis on sodium dodecyl sulphate-acrylamide gels of assembly patterns of primary and secondary variants. *a1*, 45.6.3.2 ICR 11.19, which synthesises a heavy chain of molecular weight 50,000, and the secondary variant, *a2*, 45.6.3.2 ICR 11.19 S3, which synthesises a $\gamma 2a$ heavy chain of molecular weight 55,000. *b1*, 45.6.2.4 ICR 9, which synthesises a $\gamma 2a$ heavy chain of molecular weight 75,000 and the secondary variant, *b2*, 45.6.2.4 ICR 9.9.2, which synthesises a $\gamma 2a$ heavy chain of molecular weight 55,000. Panels *b3* and *b4* show the respective heavy and light chains after total reduction and alkylation of the disulphide bridges. The assignment of H_2L_2 , H and L is done in accordance with ref. 6 and confirmed by comparative molecular weights from these and other data.

Table 2 Conversion of primary variants to secondary variants

Size and serotype of parent chain	Parent cell line	Mutagen	Primary variant: name and size of heavy chain	Secondary variant: size of heavy chain	Serotype
IgG-2b (55,000)	45.6	ICR-191	(45.6 ICR 4.68) 50,000	40,000	Negative
	45.6.3.2	ICR-191	(45.6.3.2 ICR 11) 50,000	55,000	($\gamma 2a$)
	45.6.2.4	ICR-191	(45.6.2.4 ICR 9) 75,000	55,000	($\gamma 2a$)

diminished ability of some variants (45.6 ICR 4.68, 45.6.3.2 ICR 11.19, and 45.6.2.4 ICR 9) to secrete immunoglobulin heavy chains may confer a selective disadvantage on these cells, thereby allowing us to detect secondary variants in these populations. In contrast, primary variants synthesising heavy chains of molecular weight 40,000 and 55,000 seem quite stable. In the latter case, the heavy chains are assembled well into H_2L_2 (as shown in Fig. 1, panels a2 and b2) and are subsequently secreted from the cell^{3,4}. Consequently, both primary and secondary variants of these stable types are especially valuable since they secrete myeloma protein into the sera of mice bearing tumours induced by subcutaneous or intraperitoneal injection of the variant cells. Thus, structural studies of the variant heavy chains are facilitated.

Many observations suggest that all our variants are the result of mutation. The variants are generally stable and are increased in number after mutagenesis, and the heavy chains they synthesise differ structurally from the parent. In addition, the variants we have seen, whether primary or secondary in origin, seem to fall qualitatively into the four groups shown in Table 1. These groups are defined by size of the heavy chain, assembly characteristics, and serological characteristics even though the members of each group differ somewhat by peptide mapping and, in some cases, by rate of assembly. Perhaps the quantal characteristics of the sizes of variant heavy chains produced will reflect the presence of certain genetic hot spots which are sites of rapid mutation.

On the other hand, the primary variants arise at a remarkably high incidence. For example, treatment of the parental population with $1 \mu\text{g ml}^{-1}$ of ICR-191 yields unstained clones at an incidence of 2%. One-third of these clones are synthesising altered heavy immunoglobulin chains. These incidences are extraordinary when compared to measurements in bacteria and other mammalian cell culture systems. This observation, together with the spontaneous generation of secondary variants from certain primary variants, makes us question whether the original lesion is within the structural gene dictating the parental heavy chain. It is possible, for example, that exposure to certain mutagenic agents will render a cell generally hypermutable because of an interaction with a regulatory element. It is interesting, therefore, that so far variants synthesising heavy chains of molecular weight 50,000 or 75,000, that is, those which have subsequently yielded secondary variants, have been selected only after treatment with ICR-191. The two stable types, those which synthesise short heavy chains of molecular weight 40,000 and those which synthesise γ_2a heavy chains of molecular weight 55,000 have appeared after treatment with either ICR-191 or with Melfalan^{3,4,7}, a phenylalanine mustard used in clinical treatment of human myeloma. Whether particular primary variants may have an essential instability is a question we are actively exploring.

We hope that the combination of cellular studies with the careful structural analysis of variant heavy chains will help us to analyse the genetic and molecular nature of the variations observed in these cells.

We thank Mr Richard Campbell for technical help. This work was supported by a grant from the NIH.

Annihilation of positrons in D and L isomers of various amino acids

GARAY *et al.*¹ have reported on experiments, on positron annihilation in D and L isomers of various amino acids. I show here that one of the two interpretations which they put forward to explain their results is in error, and also discuss other possible experiments which may enable clarification of the rather unusual results they have reported.

In the experiment referred to (paraphrasing the authors' description) 'crystalline samples of D and L amino acids were packed around a 0.8- μCi Na^{22} (positron) source to a thickness of 6-7 mm, and it (source plus amino acid) was placed between two scintillation counters of NE111 plastic scintillator coupled to 56-AVP photomultipliers'. The positrons either annihilate directly, probability >80% and lifetime $\tau \sim 0.2$ ns, or form singlet or triplet positronium (Ps), with lifetimes $\tau_s = 0.1$ ns and $\tau_t \sim 1$ ns (τ_t is reduced from its free space value of 138 ns by electron pickoff). Using standard fast coincidence techniques the authors find the intensity of the long-lived (presumably triplet) Ps components in D and L isomers of a series of 5 amino acids to satisfy the relation $I_L/I_D = 0.67$ (7), 0.72 (6), 0.82 (5), 0.83 (6), 0.94 (6). The numbers in parentheses are experimental errors and the results of 0.67 and 0.82 come from samples of tryptophan produced by different laboratories. The authors conclude from this data that "... D isomers of amino acids favour triplet states in the case of forward polarised β^+ particles. It seems likely from this evidence that β decay was the cause of an initial asymmetry in the racemic mixtures present on the primordial Earth".

The authors interpret these results in terms of a possible correlation between the electron velocity and the electron spin within the sample, $\langle v_a \sigma_B \rangle = K \delta_{aB}$ where K has opposite sign for L and D and $\langle \rangle$ refers to an ensemble average. They also assume that the probability of Ps formation depends on the relative velocity of electron and positron. If then the positrons have a non-zero helicity h ($h \equiv \langle \sigma(e^+) \cdot V(e^+) \rangle$ where $\sigma(e^+)$ is the e^+ spin vector, $V(e^+)$ the e^+ velocity direction, and $\langle \rangle$ refers to an ensemble average over the e^+ beam) the probability of triplet against singlet Ps formation will vary in switching from L to D. Thus one would expect that the intensity of the short and long components in the time spectrum should depend on the isomer under consideration. Note that in this interpretation it is the helicity, not the polarisation $P \equiv \langle \sigma(e^+) \rangle$ of the beam, on which I_L/I_D depends. As an instructive example to illustrate this point consider the limiting (and completely artificial) cases in which Ps formation occurs only for $V(e^-)$ parallel to $V(e^+)$ and for $K = +1$ for L and -1 for D. If we now note that the spinor direct products $\uparrow\uparrow$ or $\downarrow\downarrow$ ($\uparrow, \downarrow; \uparrow, \downarrow$ refer to e^-, e^+ spins) give half triplet and half singlet decays one may easily show that the situation $P=0$ for $h = +1-1$ yields $I_L/I_D = 2$ or 0.5 while $h = 0$ yields $I_L/I_D = 1$ for any P.

We now remark that whatever the correlation between Ps formation and relative velocity and whatever the actual (presumably small) value of K is, $h \approx 0$ at e^+ kinetic energies (~ 5 eV-15 eV) characteristic of Ps formation. This can be demonstrated by noting that experimental² and theoretical^{3,4} studies have shown that if a beam of electrons (or presumably positrons) impinges on a surface with energy E_0 (10^4 eV $< E_0 < 10^6$ eV) the beam will have a completely diffuse nature (velocities

completely random) by the time it has penetrated a distance where the mean energy of its constituent particles is still $>3,000$ eV. This may be most readily arrived at by applying formulas (4) and (5) of Archard⁴ for the case $Z \sim 3-10$ (the result is insensitive to Z). Since at energies $\leq m_0c^2$ ($=0.5$ MeV) σ does not follow V (see ref. 5) it follows that $h \approx 0$. Note that the energy range 10^4-10^6 eV brackets the energy of almost all e^+ emitted by ^{22}Na . In addition, though it is not relevant to the problem, we point out that the geometry of the experiment gives $P \approx 0$ as well.

We conclude that the effect seen by Garay *et al.* is in all likelihood not a result of positron polarisation or helicity. If real it may be a result, as Garay *et al.* recognise, of the inhibition of Ps formation and/or greater triplet quenching in L as opposed to D, possibly because of an undetected chemical impurity. It may also be caused by some slight difference between the solid state structure of the L and D crystals. If so, a new simple, non-destructive and highly sensitive method of detecting such impurities is now available. Experiments to determine the dependence (or lack thereof) of I_L/I_D and the overall Ps formation rate on P and possibly on h are now being started. To try to investigate the dependence of I_L/I_D on h we may use the low energy positron beam available in our laboratory, if the polarisation of the beam is sufficiently high.

I thank G. W. Ford, D. W. Gidley, A. Nudelfunden and E. Rosenberg for useful conversations, and the NSF for support.

Conformations of double-helical nucleic acids

A KNOWLEDGE of possible conformational states of double-helical nucleic acids is fundamental to an understanding of how they work^{1,2}. Models for a series of conformations have been made on the basis of X-ray data³⁻⁵. Investigations of nucleic acids in solution point to the existence of a continuum of forms but do not make possible the quantitative determination of the conformational parameters. Here, theoretical investigation of the intramolecular interaction energy as a function of conformational parameters and a search for minimal energy regions in the space of these parameters become essential.

Two families of nucleic acid conformations are known, the A and B families, which differ by the mutual position of the base pairs, the conformational angles in the ribose-phosphate backbone and the conformation of the ribose ring. This last is a major factor determining whether a double-helical structure belongs to the A or B family of conformations. The C_2' -endo conformation in the A family and the C_2' -endo or C_3' -exo conformation in the B family are assumed⁴. Data on the conformation of the ribose ring cannot be obtained from the diffraction patterns of nucleic acid fibres. The ribose conformation is taken from X-ray data for the nucleic acid components. The ribose ring in double-stranded helical nucleic acids is, however, in different surroundings from that in monomer crystals. It may be rearranged in the course of transitions between both the families and the different forms of a family. In this connection, the intramolecular interaction energy of double-helical nucleic acids was considered in our work (unlike the recent

works^{6,7}) with an account of conformational possibilities of a ribose ring.

We calculated the intramolecular interaction energy for the regular double-helical polynucleotide containing rigid Watson-Crick pairs as a function of eight conformational variables. Four of them determine the mutual position of the base pairs (D is the distance from the pair centre to the helical axis, d the pair-pair distance along the helix axis, θ the tilt angle of the base pairs to the plane perpendicular to the helix axis, τ the rotation angle of one pair with respect to another around the helix axis), four others ($OC_1'C_2'$ and $C_1'C_2'C_3'$ bond angles and dihedral angles τ_1 and τ_2) determine the conformation of a ribose ring. The bond angles of a ribose ring were considered as variables in contrast with other bond angles. The bond lengths were fixed. The eight variables with the above-mentioned

Fig. 2 Projections of the B-family bottom position for the poly(dA).poly(dU): a, on the (D , θ); and b, on the (D , τ) planes. The known forms are marked.

constraints completely determine the conformation of a regular polynucleotide.

Dihedral angles of sugar-phosphate backbone were determined by means of a procedure which resembles one of Go and Scheraga's⁸. The van der Waals' interactions were calculated by the atom-atom potential function method⁹. The Lennard-Jones potentials were used; the validity of parameters was verified by calculations on nitrogen base crystals. The heats of sublimation and lattice constants of a number of aromatic compound crystals were reproduced (V.I.P., unpublished). The tension energy of the bond angles in the ribose ring was assumed to be proportional to the square of the deviation of these angles from the tetrahedral ones. Previously¹⁰ we studied the interaction energy between the base pairs as a function of parameters determining their mutual position in a double helix. We detected a limited region in the space of these parameters

energetically allowable with these parameters. Thus the region of the eight-dimensional conformational space which should be investigated might be drastically diminished. The many-variable function minimisation procedure was used for searching for the energy minima.

The calculations showed the existence of two valley-like regions of minimal values on the energetic surface. One of them corresponds to the A family of nucleic acids, the other to the B family. The energy variation along the bottom of each valley is rather small; the energies are the same for both valleys up to 1 kcalorie mol⁻¹. The points which correspond to the models constructed by means of X-ray data are placed in the conformational space near the lines which describe the position of the bottom of a valley. There is a systematic deviation towards the lower D values for the points which correspond to the models of the A forms. But if $D = 4.7$ Å is fixed (like the models of the A forms) the line in the conformational space which corresponds to the bottom of this valley passes through the experimentally determined forms of the A family. This displacement is connected with the intramolecular interaction energy change by 1–2 kcalorie mol⁻¹. It is not excluded that the double-helical macromolecule contracted in diameter due to intermolecular interactions with neighbouring molecules in fibres. The A family is characterised by a nearly linear relationship between the parameters d and θ as well as d and τ (Fig. 1). The forms both with great and with small distances between the pairs along the helix axis are sterically allowed. The position of the valley bottom corresponding to the B family is characterised by the constancy parameter d (approximately 3.4 Å). For the B family, τ increases almost linearly whereas θ strongly diminished with the decrease of D in accordance with the

Fig. 1 Projections of the A-family bottom position for the poly(dA).poly(dU): a, on the (d , θ); and b, on the (d , τ) planes ($D = 4.7$ Å). The known forms are marked.

Fig. 3 Dependence between the changes in the conformational parameters of deoxyribose ring and the position of the structure on the valley bottom for A (a) and B (b) families. $\tau_0, \tau_1, \tau_2, \tau_3, \tau_4$: rotation angles around $O'-C_1', C_1'-C_2', C_2'-C_3', C_3'-C_4', C_4'-O'$ respectively; d_2 and d_3 : the derivations of the C_2' and C_3' atoms from the plane of other atoms of a sugar ring. The positive values corresponds to deviation towards C_5' atom.

results of X-ray studies (Fig. 2) A systematic deviation towards the lower θ values can be seen for the points which correspond to the models of B family forms but there is a tendency to raise absolute value of θ in recent models

A correlation is observed between the disposition of the base pairs which corresponds to the optimal energy values and the sugar ring conformation (Fig. 3). The last one resembles the standard C_4' -endo or C_3' -endo conformation for those parts of valleys where models based on X-ray studies exist. The ring deformation in the B family is more pronounced than that in the A family. At the positive D values both C_2' and C_3' atoms deviate from the $C_1'O'C_4'$ plane towards C_5' (Fig. 3b).

An energetically unfavourable region exists in the conformational space between the A and B family valleys. The minimal steric barrier between the two families is about 3 kcalorie mol⁻¹.

The relationships between the conformational parameters of a double-helical polynucleotide which we have obtained may be used to detect the degrees of freedom of the system for the analysis of its behaviour under the effect of weak perturbations (as against intramolecular interactions). Different double-helical nucleic acid conformations may exist in different conditions in the interaction with some biologically important compounds.

We thank the head of our laboratory A. I. Kitaigorodskii for his interest and discussions.

matters arising

Particle creation and Dirac's Large Number Hypothesis

In a recent paper¹ Steigman claims to show that the creation of matter as postulated by Dirac² is unnecessary. In particular he claims that a theory with a gravitational constant G varying as t^{-1} automatically implies that the number of nucleons within the horizon should increase as t^2 . If so, Dirac's hypothesis that $N \sim t^2$ must be due to spontaneous matter creation becomes unnecessary. We here show Steigman's claim to be incorrect.

First, note that within Dirac cosmology the present radius of the Universe varies as $R \sim t$. Assuming such a time dependence holds in the very early Universe, as Steigman does, then there is no horizon since the integral

$$d_H(t) \equiv cR(t) \int_0^t \frac{d\tau}{R(\tau)} \quad (1)$$

defining the horizon distance diverges logarithmically. Therefore, any increase of mass, M , with time, t , no matter how, must be ascribed to spontaneous creation since no matter is entering the space, V , across the expanding horizon.

We now show how matter creation must be an independent hypothesis for Steigman's equation (1) to be correct. As shown in ref. 3, the correct Einstein equation in atomic units is given by

$$\left[\frac{\dot{R}}{R} + \frac{\dot{\beta}}{\beta} \right]^2 + \frac{k}{R^2} = \frac{8\pi}{3} \bar{G} \bar{\rho} \beta^2 \quad (2)$$

Here β is the gauge function which varies asymptotically as t^{-1} , and \bar{G} and $\bar{\rho}$ are given in Einstein units. In Einstein units \bar{G} is constant, and $\bar{\rho}$ is given by

$$\bar{\rho} = \bar{M} / \bar{R}^3 \quad (3)$$

where, following Dirac², \bar{M} and \bar{R} are constant so $\bar{\rho}$ is constant. Since $\bar{R} = \beta R$, where \bar{R} and R are the radii of the Universe in Einstein and atomic units, respectively, equation (2) becomes

$$G\bar{\rho}\beta t^2 = \text{constant} \quad (4)$$

where we have used $G = \bar{G}\beta \sim t^{-1}$ and

$R(t) \sim t$. Equation (4) coincides with Steigman's equation (1) only if we define

$$M/R^3 \equiv \rho \equiv \rho\beta \equiv \bar{M}\beta/\bar{R}^3 \quad (5)$$

Since $\bar{R} = \beta R$ it follows that the mass entering the definition of ρ , that is, M , must be related to the constant mass \bar{M} by the relationship

$$M = \bar{M}/\beta^2 = \bar{M}t^2 \quad (6)$$

which explicitly shows matter creation.

The error in Steigman's reasoning lies in the postulate of his equation (1) which does not have the backing and theoretical framework that justifies and correctly defines each quantity in the equation. One cannot simply postulate the existence of a relationship of the type

$$G\rho t^2 = \text{constant} \quad (7)$$

and then take $G \sim t^{-1}$ assuming, as Steigman does, that ρ does not contain matter creation. If such a theory exists, as it might well do, it cannot be presented under the name Dirac cosmology. In fact, the full Dirac theory yields a relationship like equation (7) only if ρ is defined by equation (5), that is, if it already contains matter creation.

The second part of Steigman's criticism is invalid for a different reason. Here he points out that Dirac's large Number Hypothesis (LNH) implies such things as the fact that there can be no primordial nucleosynthesis, and that for $T \sim 10^{10}$ K the number of baryons in the Universe is of order unity.

In fact Dirac² has repeatedly stressed that the LNH is an asymptotic theory valid only for relatively large times over most of the age of the Universe, but not necessarily at very early epochs. Thus the second part of Steigman's paper strongly supports Dirac's statements and in no way invalidates the LNH.

In summary, Steigman's claim that Dirac's LNH does not require particle creation is wrong because he has assumed that which he was seeking to prove, that is that ρ does not contain matter creation. Steigman's claim that Dirac's LNH leads to nonsensical results in the very early Universe is superficially correct, but this only supports Dirac's contention that the LNH may not be valid in the very early Universe.

³ Adams, P. J., Canuto, V., Hsieh, S. H. and E. Tsiang, *Phys. Rev. D* (in the press).

STEIGMAN REPLIES—In Dirac's original cosmology the scale factor varies as $R \sim t^{1/3}$ (there is a possible confusion by Canuto *et al.* between 'scale factor' and 'radius of the Universe'). In this model there is a horizon and the results and conclusions of my paper apply. There are, of course, a large number of possible modifications of Dirac's original model. In the variation chosen by Canuto *et al.*¹ ($R \sim t$) there is no horizon. In this model then, there are always an infinite number of particles 'in the Universe' and, clearly, Dirac's Large Number Hypothesis (LNH) cannot apply.

Canuto *et al.* argue that several of my criticisms of Dirac's theory are invalid because the LNH is an 'asymptotic' theory. It is certainly not clear why this should be so; why do the equations in Canuto *et al.* not apply for all times? A cosmological theory which only predicts the present epoch is of questionable value.

The pre-palaeozoic basement in south-eastern Scotland and the southern uplands fault

BASAMENT xenoliths in Carboniferous volcanics in the vicinity of Partan Crag along the south side of the Firth of Forth have been used to infer the character of the immediately underlying basement by Upton *et al.*¹. These

xenoliths are probably representative of a subjacent basement but they cannot be unequivocally regarded as reflecting the basement character beneath the geological Midland Valley of Scotland, in a larger structural sense, as has been argued. Although the south-east boundary of the Midland Valley, as a geological feature, has been commonly taken along the Lammamuir Fault², it is likely that this fault may only be a shallow and relatively insignificant feature at depth. The magnetic map³ shows that the major geophysical break or linear, which, to the west, follows the course of the Southern Uplands Fault, passes near to or north of Partan Crag. The prominent magnetic linear lies everywhere between the Southern Uplands Fault and the faults associated with the structural hinge that passes from near Girvan to Edinburgh⁴. This suggests that either or both of these structures on the surface reflect the true position at depth of a significant crustal structure, which should be termed the Southern Uplands Line. It is suggested that the use of the Southern Uplands Fault alone as a single line taken as marking the surface expression of a major deep seated structure is unrealistic.

Along the south-east part of the Midland Valley, the magnetic linear³, which along the south-west margin is nearly coincident with the Southern Uplands Fault, diverges to the north from the geological southern margin of the Midland Valley in the vicinity of Dalkieth and passes near the southern margin of the Firth of Forth. There is a north-south distance of up to 18 km between the Southern Uplands Fault to the south, and the southern margin of the structurally more significant magnetic linear. The broad, open pattern of extensive, regular magnetic signature with shallow gradients, which can be traced through the Southern Uplands³, clearly extends beneath and North of the Lammamuir (Southern Uplands?) Fault and strongly suggests that rocks which are magnetically characteristic of those below the Southern Uplands pass northwards to at least the magnetic linear zone. This recognition of the probable northwards extent of the Southern Uplands basement would place the Southern Uplands basement very near to Partan Crag. It could then be argued that the basement rock types noted by Upton *et al.*¹, probably are characteristic of the basement beneath the Southern Uplands. This would be consistent with the basement character suggested from the western end of the Longford-Down Massif in Ireland⁵, which is a geophysical and probable geological extension of the Southern Uplands^{6,7}.

As it is uncertain whether the in-

ferred pre-Dalradian basement of Upton *et al.*¹ underlies the Midland Valley or the Southern Uplands tectonic zones, it would probably be unwise to be too specific about structural reconstructions involving the precise location of the landmass lying to the

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

south of the Dalradian sedimentary basin. The relationship of the xenoliths to the basement area they have been derived from must first be established with greater precision. If there is a significant difference between the basements beneath the Midland Valley and the Southern Uplands in SE Scotland, and this is not altogether certain, then the xenoliths could probably be better regarded as representing the basement to the south of the Southern Uplands line, rather than that to the north, beneath the Midland Valley.

Running Dinosaurs

ALEXANDER'S¹ use of stride length and footprint size to determine from trackways the speed of terrestrial vertebrates will greatly increase our understanding of dinosaurian behaviour. None of the trackways he cited were of large running dinosaurs, although he did not suggest that large dinosaurs never ran. We herein cite one such example, and another of a very fleet dinosaur that was not running.

In a trackway of a giant bipedal ornithischian from the Cretaceous (Campanian) of Colorado² the length of the footprint (l) is 0.86 m and the stride (λ) is 9.25 m. Similar footprints have been referred to the Hadrosauridae, the only large bipedal ornithischians then present in North America (ref. 3: footprint in collections of Drumheller and District Museum, Alberta). Combining Alexander's method to find hip height (h ; $h=4l=3.44$ m) with Colbert's⁴ method for estimating the weight of an *Anatosaurus* specimen (where $h=2.25$ m), it is apparent that the Colorado animal weighed about 11 tonnes or as much as two bull African elephants combined. This exceeds by a factor of nearly three the weights obtained for hadrosaurids from the northern interior of North America⁵, but is less than what we estimate (13.8 t) for a giant lambeosaurine hadrosaurid from Mexico⁶. We obtained our estimate using Colbert's⁴ method and considering a 1/12 scale model of *Hypacrosaurus altispinus* (NMC 8501) with a volume of 1,372 ml as a 1/17.5 scale of the Mexican lambeosaur (based on humeral lengths in the two specimens). According to Alexander's formula, the Colorado animal was running at a velocity of 7.54 m s^{-1} (27.1 km h^{-1}).

Anatomically, it has been suggested that some ornithomimids weighing about 140 kg could attain speeds of 80 km h^{-1} (ref. 6). (A 1/6.5 scale model of the ornithomimid *Dromiceiomimus breviterius* (NMC 12228) has a volume of 564 ml, yielding a weight of 154.9 kg, using Colbert's⁴ method.) In an ornithomimid trackway from the Campanian of Alberta⁷ λ is 1.88 m and we estimate h to be 1.22 m, indicating a speed of 1.77 m s^{-1} (6.4 km h^{-1}). According to Alexander¹, this animal would have begun to run when λ/h reached 2, or at a speed of 2.75 m s^{-1} (9.9 km h^{-1}). At a speed of 80 km h^{-1} , prints from the same foot (λ) would be 8.6 m apart.

In our opinion, trackway data so far obtained are not yet adequate for generalisation on dinosaurian metabolism.

reviews

Membrane-bound glycoproteins

Gilbert Ashwell

Membrane Glycoproteins. A Review of Structure and Function. By R. Colin Hughes. Pp. 367. (Butterworth: London and Boston, Massachusetts, March 1976.) £15.00.

FOR years, the presence of carbohydrates covalently linked to protein molecules was regarded with disbelief, dismay, or even indifference, by classical protein chemists intent on structural determination. Eventually, as a result of the brilliant pioneering studies of men such as Dische, Neuberger, and Winzler, delineation of the chemical bond between carbohydrates and proteins was accompanied by a growing awareness of the role of surface glycoproteins as 'informational macromolecules' mediating a variety of biological phenomena on a cellular level. As a consequence, the past decade has seen a logarithmic growth in the number of publications documenting the ubiquitous presence and complex interactions of membrane-bound glycoproteins.

It is to this problem that the author has addressed himself in a valiant and impressive effort to organise, systematise, and summarise the diffuse and multidisciplinary reports which comprise the current literature on glycoproteins. It is, perhaps, the latter consideration which epitomises the difficulty in maintaining an integrated perspective on the relevance of findings in widely diverse scientific disciplines. Few investigators, actively pursuing their immediate research interests, are either willing or able to devote the time and effort necessary to master the vast amount of potentially relevant information available in journals and disciplines with which they have an only peripheral acquaintance.

Fortunately, that task has been brilliantly accomplished in this monograph. Beginning with a detailed examination of the methodology used in the detection and distribution of membrane glycoproteins, a number of well referenced tables are provided to summarise the important properties and chemical composition of plasma membranes isolated from various species, the surface characteristics of the commonly used tissue culture lines, and the availability of specific glycosidases useful in the analysis of terminal carbohydrate residues. Although

the major thrust of current studies on cell surface glycoproteins has been directed mainly at the outer surface of the cell, the membranes of the sub-cellular organelles are similarly rich in glycoproteins, and their participation in intracellular phenomena is largely speculative. This problem is considered in some detail in a provocative chapter which summarises the available information and seeks to interpret current views on the genesis of primary and secondary lysosomes.

Following this, the role of oligosaccharide determinants involved in human blood group activity and the chemical nature of the ABO and MN antigens is reviewed. The judicious use of illustrative diagrams and chemical formulae facilitate comprehension of the necessarily cumbersome nomenclature used for carbohydrate chains. This section also provides a good overview of the chemistry of the histocompatibility antigens which is quite adequate for the non-specialist reader; extensive referencing is included for those seeking more detailed information. A minor point that requires comment is the statement (p126) that histocompatibility antigens are precipitated by anti-H antisera. To the best of this reviewer's knowledge this is not quite accurate in that a second precipitating agent is always required.

The middle portion of the book covers the extensive literature on lectins and their fascinating reactivity

toward the membrane glycoproteins of the lymphocyte, with emphasis on the biological implications of cellular transformation. Finally, the current status of the biosynthetic and degradative mechanisms involved in the overall metabolism of glycoproteins is presented in elaborate detail. Especially noteworthy is the section on lipid intermediates which is written with commendable lucidity and insight. The discussion on the role of specific carbohydrates in the 'recognition' phenomena is thoughtful and well-documented. The speculation (p297), however, that the hepatic binding protein participates as a glycosyltransferase in the adhesive properties of membranes, as described by Roseman, is unlikely since the purified binding protein was shown to be devoid of both sialyl- and galactosyl-transferase activity.

In summary, this monograph provides an impressive synthesis of the glycoprotein literature up to and including 1974. The author has earned the gratitude of innumerable investigators in diverse disciplines, who are concerned with the biochemical basis of membrane function and its role in cell biology.

Gilbert Ashwell is Chief, Laboratory of Biochemistry and Metabolism, US Public Health Service, National Institutes of Health, NIAMDD, Bethesda, Maryland.

Membrane recipes

Biochemical Analysis of Membranes. Edited by A. H. Maddy. Pp. ix+513. (Chapman and Hall: London; Halsted: New York, July 1976.) £16 50.

THIS is a most timely book. In recent years a considerable expertise has grown up in membrane biology. But all the expertise in the world is wasted unless studies are carried out using pure samples of known origin. For studies of molecular events in membranes, the problem boils down to the isolation and characterisation of single membrane fractions with minimal loss of intrinsic components or gain of extrinsic components. Although progress in this direction has been fairly rapid, the development of suitable procedures

has remained more of an art than a science: hence the need for a book of this kind.

What Dr Maddy has done is to persuade a number of authors to present background discussion and experimental recipes for the preparation and analysis of the most common membranes and membrane constituents. The general format of each chapter is excellent. The first part consists of a comparative literature survey and the second of fully detailed experimental procedures, aimed largely at the level of the novice. The only real test of a collection of recipes is, of course, to try them in the kitchen, and this I have not yet had a chance to do. The couple of procedures published here

with which I am familiar, however, include all the useful tricks, and the others have an authoritative look about them.

The first section of the book consists of procedures for the isolation of membranes, and includes chapters on Mycoplasma membranes (Razin and Rottem), surface membranes (Neville), mitochondrial membranes (Sottocasa), endoplasmic reticulum (De Pierre and Dallner) and nuclear membranes (Harris and Agutter). The only pity here is that there is nothing on membranes of bacteria such as *Escherichia coli* or on micro-organisms such as *Tetrahymena*, both of which are proving of importance in studying correlations between membrane structure and function.

The second section of the book is concerned more with the analysis of membranes, and includes chapters on the solubilisation of membranes (Maddy

and Dunn) and on the analysis of membrane proteins (Dunn and Maddy), lipids (Veerkamp and Broekhuysse) and carbohydrates (Cook). These are followed by some more peripheral, but no less interesting chapters on the applications of phospholipases (Zwaal and Roelofsen), on immunochemical gel precipitation techniques (Bjerrum and Bog-Hansen) and on protein labelling (Hubbard and Cohn).

It is perhaps a sign of how far the study of membranes has progressed that a book of this kind can be written; and there can be few working with membranes who would not gain by browsing through it. Finally, there is a coherence about the book which it is rare to find in an edited volume, and for which the editor deserves high praise.

A. G. Lee

Dr Lee is a lecturer in the Department of Physiology and Biochemistry at the University of Southampton, UK.

Transition metal compounds

Methodicum Chemicum Volume 8 Preparation of Transition Metal Derivatives. Edited by Kurt Neidenzu and Hans Zimmer. Pp. x+579. (Academic: New York, San Francisco and London, 1976.) \$110; £67.10.

THIS text details published and proven methods for the preparation of transition metal compounds. In general, one chapter is devoted to each of the thirty d-transition elements; the lanthanide and actinide groups of elements each merit one chapter, a summary of ferrocene chemistry is included; and aspects of carbonyl, metallocene, and heteropolyanion chemistries are reviewed separately. The material for each chapter is classified in order of increasing oxidation state, a reasonably good index is provided and no real difficulty should be encountered in using the volume as a reference source. Each chapter is referenced in a reasonably comprehensive manner and nearly 7,000 original publications and review articles are cited in all. Some 29 authors have made one or more contributions, and, in several instances, these chemists are internationally recognised as authorities on their chosen topic.

Despite the considerable collective talent and effort involved in the preparation of this work, however, several reservations must be expressed when considering a recommendation to purchase this expensive volume. The most serious of these reservations results from the inherent nature of this work, which attempts to describe contemporary synthetic transition metal chemistry

in less than 600 pages. Since the space devoted to a particular element is no more than fifteen pages, the book reads like a laundry list. The description of the preparation of any particular compound, or group of compounds, is covered in one sentence of the 'add A to B to produce C' variety, with no details of the yield, purification procedure(s), necessary precautions, or properties of the compound(s) being given. As none of the material is original and the authors have been critical only in their selection of the material to be included, much of the information presented is readily accessible to the initiated inorganic chemist in standard and specialist texts and review articles. These criticisms are all the more serious since, due to certain unspecified difficulties, a considerable delay has occurred between the submission of the manuscripts and their publication, so that the coverage of the literature ends at 1970.

This volume is an extremely useful, if somewhat outdated, reference source for synthetic routes developed for the preparation of a wide range of transition metal compounds. In view of the reservations outlined above, the inorganic research chemist could spend the amount of money involved more wisely by purchasing a collection of other texts. The non-specialist inorganic chemist, and other scientists interested in the preparation of inorganic compounds, should, however, find this compilation of considerable value.

C. David Garner

Electrophilic halogenation

Electrophilic Halogenation. By P. B. D. de la Mare. Pp. xi+231. (Cambridge University: Cambridge, 1976.) Hardcover £10.50; softcover £4.50.

ALTHOUGH some discussion of the importance and mechanism of electrophilic halogenation is to be found in most undergraduate texts, there is a need for an up-to-date, detailed and unified discussion of such reactions.

In this book electrophilic halogenation is covered from a mechanistic viewpoint. It is a complex area where the problems of reactivity, regioselectivity, stereoselectivity, product multiplicity and the nature of the halogenating species all have to be taken into account. The author, who has been an active research worker in this area for some thirty years, adopts an approach which considers the formation and fate of the carbonationic species produced by attack of electrophiles in general on unsaturated compounds, both aromatic and aliphatic. The basic patterns which emerge are then elaborated for each of the halogens and their derivatives in turn. Topics such as the acid and base catalysed α -halogenation of carbonyl compounds are covered in a chapter on miscellaneous electrophilic halogenation, and there is also a chapter on electrophilic halogenation of aromatic heterocycles. Introductory chapters provide the necessary background in physical organic chemistry and describe the halogens and their derivatives.

In keeping with the Cambridge University Texts philosophy, the level of the book is intended to suit final year undergraduate and early postgraduate students. The book contains many references to the original literature and is clearly written. It will nevertheless be demanding at the level intended, concentrating as it does on physical organic rather than descriptive aspects of the subject. The undergraduate may also feel that the area of chemistry covered for the price of the book is somewhat limited; and indeed the book may have had a wider appeal if the scope had been broadened to cover either electrophilic addition and substitution in general, or halogenation in general. The latter suggestion has much to commend it since free radical halogenation is also very important and frequently competes with the electrophilic process.

R. C. Storr

Dr Storr is a Lecturer in the Department of Organic Chemistry at the University of Liverpool, UK.

Protein polymerisation

Thermodynamics of the Polymerization of Protein. (Molecular Biology: An International Series of Monographs and Textbooks). By Fumio Oosawa and Sho Asakura. Pp. viii+204. (Academic: London and New York, March 1976) £6 80; \$16.75.

NATURE constructs the elementary blocks composing the constituents of living matter from small inanimate molecules which abound in our environment. The synthesis of the building blocks as well as of the highly specific functional macromolecules which they eventually form, is a complex process. It proceeds with the aid of elaborate machinery, specific templates and an ample supply of energy. Classical biochemistry and molecular biology study this elaborate process of creation and of disposal of biological macromolecules. It may have come as a surprise that spontaneous assembly of biological structures, unassisted by accessory means, could proceed as well. Indeed there exists an enormous variety of structures which form spontaneously from simpler protein constituents. For this process, which is often reversible and satisfies the laws of thermodynamics, Caspar and Klug have coined the term self-assembly.

The book by Oosawa and Asakura illustrates the impressive contribution of the Nagoya school to the problem of protein polymerisation. In addition to thermodynamics, kinetics, structural requirements, allosteric control, polymorphism and internal motility and flexibility of assembled structures are treated as well. Unfortunately, the bulk of the discussion is restricted to studies of actin and flagellin polymerisation from the authors' and other, not too distant, laboratories. About 76 entries in the authors' index are only perfunctorily listed in the list of references at the end of the volume. Although this represents a useful sectioned compilation, it does not provide the critical discussion (on varied approaches to an interesting problem) one expects from an authoritative monograph. For instance, on page 60 it is stated that in the trimer-disk transformation of TMV protein the enthalpy increases by about 77 kcalorie mol⁻¹, and another experiment gives 14–38 kcalorie mol⁻¹ for the same process. The possible causes of this discrepancy, deriving from the analysis of the dependence of equilibrium constants on temperature on the one hand and calorimetric measurements on the other hand, are not discussed.

In chapter 10, the reader not familiar with the subject may be misled with respect to the chronological development of the use of quasi-elastic light scattering in the study of the dynamics of macromolecular structures. I have doubts whether the reader to whom this monograph is addressed will easily follow the calculations in chapters 6 and 10, and appreciate their significance in terms of the experiments performed. The symbols in Table 3 on page 87 are intelligible to crystallographers and the statement on page 97—"Thermodynamic analysis of the polymerisation equilibrium of sickle cell hemoglobin is not enough to be compared with the above result"—is cryptic.

There are some printing errors, but not excessively many. The illustrations are clear and attractive. The cost is reasonable and should not prevent interested libraries as well as individuals from acquiring this compact, if somewhat one-sided, introduction to a topical field.

Henryk Eisenberg is a member of the Polymer Department at the Weizmann Institute of Science, Rehovet, Israel.

Below 1 K

Refrigeration and Thermometry below One Kelvin. By D. S. Betts. Pp. x+283. (Sussex University: Sussex, 1976.) £8 00.

ONE of the most surprising things about research at very low temperatures, to the uninitiated, is its continuing interest and richness. With each further improvement in technology, enabling physicists to push even closer to their unattainable goal of the absolute zero of temperature, there have emerged new and fascinating phenomena to be observed, quantified, and pondered about. The most significant area of technical development over the past decade has undoubtedly been that of 'He-He dilution refrigeration, which has now reached the point where commercially available machines are capable of maintaining a sample indefinitely at temperatures near 10 mK, thus providing a convenient starting temperature from which the 1 mK region becomes immediately accessible through the addition of, for example, an adiabatic demagnetisation stage. Near 1 mK, of course, are the extraordinarily complex 'new phases' of liquid ³He which, with their superfluidity, magnetism and anisotropy, will continue as a challenge to the physicist

for many years to come. At still lower temperatures, in the as yet virtually unexplored region around 0.1 mK, there is the beckoning prospect of nuclear ferromagnetism.

Dr Betts' book, explaining how to do the experiments, is intended as an introduction for MSc and PhD students, and other beginners whose research involves making measurements below 1 K. The first half of the book describes how to achieve these low temperatures, and consists of six chapters covering ³He and ⁴He evaporators, ³He-⁴He dilution refrigerators, Pomeranchuk cooling, and the adiabatic demagnetisation of paramagnetic salts and nuclei. Less popular techniques such as vortex refrigeration have (not unreasonably) been omitted. Having produced a low temperature the next problem is, of course, that of measuring it. Accordingly, the second half of the book is devoted to a detailed survey of the numerous methods which are available, involving measurements of vapour pressure, paramagnetic susceptibility, nuclear magnetic resonance, electrical resistance, capacitance, thermoelectric e.m.f., electrical noise, the Mossbauer effect, and anisotropic radioactive decay.

The various techniques are outlined with impressive clarity, including a useful amount of mathematical detail, and there are copious references both to review articles and also to the original literature. To keep one's feet firmly on the ground, the book is permeated with valuable numerical information both in graphical and in tabular form, the extensive compilation of data on commonly used paramagnetic salts being a particularly striking example. The index is skimpy, but the careful and logical arrangement of material means that elusive topics can usually be traced fairly rapidly by consulting the table of contents. There is inevitably a substantial overlap in coverage with O. V. Lounasmaa's *Experimental Principles and Methods Below 1 K* (Academic, London 1974). Quite apart from its somewhat different style and emphasis, however, Dr Betts' book has the advantage of being two years more up to date, a factor not to be ignored in this rapidly developing field.

The book succeeds admirably in its stated purposes. It will also be a valuable source of reference for everyone working below 1 K, and most especially for those aspiring to join, in Dr Betts' phrase, "the new army of nuclear coolers... marching into the submillikelvin region."

P. V. E. McClintock

Dr McClintock is a Lecturer in Physics at the University of Lancaster, UK.

Genes or environment

Heredity, Environment, and Personality: A Study of 850 Sets of Twins By John C. Loehlin and Robert C. Nichols. Pp. xii+202. (University of Texas. Austin, Texas and London, 1976.)

MODEST numbers of twins, carefully sampled and personally investigated in clinical detail, sometimes over a period of years, have an acknowledged place as a valuable if limited research method, particularly in the field of psychiatric abnormality. Attention has recently been drawn, however, to the need for large samples for the adequate study of genetic and environmental influences on ability, personality and interests in the normal population. The present study reports data on some 2,000 variables collected from 850 pairs of twins, not one of whom was personally seen by the authors. The information was obtained from examination results and from questionnaires sent by post to the twins and their parents.

The subjects were those twins who participated in the National Merit Scholarship Qualifying Test taken each year by about 600,000 American high school students at the age of 16 or 17 and who completed the postal questionnaires. The authors clearly discuss the effect of possible biases caused by diagnosis of zygosity by questionnaire, selection for academic ability and willingness to cooperate, and the usual excess of identicals and females found in such samples.

They present data and discuss differences between twins and non-twins, and examine in detail early environmental experiences such as dressing alike, parents treating the twins alike, and interpersonal relationships. None of these had much, if any, influence on the resemblance found. The authors conclude that the environment "operates in remarkably mysterious ways, given traditional views on personality and motivational development".

Not surprisingly, identical twins were no more alike than fraternal twins in matters such as race—or their opinions about racial integration. In most measures, however—whether single items, clusters, or the scales of a test such as the California Psychological Inventory—identicals were usually correlated about 0.20 higher than fraternal twins. On ability measures, intrapair correlations clustered around 0.75 and 0.55 in the two kinds of twins, personality measures, 0.50 and 0.30, and measures of self-concept and interests, 0.35 and 0.15.

The authors' main conclusion, that the almost ubiquitous genetic influence is roughly equal in degree for all traits, is admittedly controversial. Furthermore, some of the statistical analyses require critical interpretation, and little attention is given to which traits are influenced by the same genes. Useful appendices presenting the questionnaires and the intraclass correlations for the twins on each variable are fertile soil for the interested twin researcher. The book can be recommended for its lucid, readable presentation and discussion of the authors' own data and the relevant literature.

Gregory Carey

Insect clocks

Insect Clocks (International Series in Pure and Applied Biology. Division. Zoology, Vol. 54.) By D. S. Saunders. Pp. viii+279. (Pergamon: Oxford and New York, July 1976.) £9.25.

THE study of biological clocks is one of those areas of the biosciences that truly straddles the plant and animal kingdoms. The existence of clock-like processes is apparently universal in eukaryotic life, and the clocks of phylogenetically widely separated species exhibit remarkably similar characteristics. Whether this indicates evolutionary convergence or a common, primitive root is not clear, but what it does indicate is why the study of biological clocks has been, and must be multidisciplinary.

The need for a monograph on the clocks of insects may therefore not be immediately apparent. Its justification lies in the simple fact that in no other single order of organisms has so much research been done on so many different kinds of clock. Herein lies the strength of *Insect Clocks*: it provides a comprehensive cover of 'chronobiology' (the subject's American name) in a microcosm.

The book starts off on circadian (that is, 24-h) rhythms, in individuals (chapter 2), in populations (chapter 3), and in physiology (chapter 4). This separation is not entirely happy because rhythms exhibit the same characteristics at whatever level of organisation they occur, so phenomena such as temperature compensation, entrainment and phase-response curves have

to be considered three times over, and the treatment, although thorough, is unnecessarily fragmented.

More than half the book, however, is devoted to insect photoperiodism—that is, the reactions of insects to seasonally changing daylength. Here, the author's touch is sure and his exposition and explanation first rate. Biologists of any specialisation wishing to understand the involutions of this tortuous subject could go a long way before finding a more comprehensive or better account. Whether this otherwise admirable explanation is aided by the chronobiologists' addiction to algebraic jargon is another matter. For example, it is simply irritating, rather than informative, to be told eight times in as many pages (8–16) that τ is the symbol for the free running period of rhythms; and does it help to be given the equation $\tau - T = \Delta\phi$, by way of parenthetical expansion of the perfectly clear phrase "... entrainment is effected by discrete apparently instantaneous phase-shifts ..." (p38)? There is a great deal of such symbolising, much of it seemingly unnecessary.

The author unashamedly sticks to insects, his self-confessed lifelong passion. Although this single-mindedness provides the book with its satisfying unitary structure, it does afflict it with an element of tunnel vision. This has prevented the author from considering any of the recent exciting work on the fundamental mechanisms of circadian oscillators, presumably because that work concerns plants, protista and molluscs. Very little is offered on the mechanisms of oscillators in general (the word 'membrane' does not appear anywhere in the otherwise full index, for example), and even on insect clock mechanisms the coverage is less thorough than in some recent reviews. The reader looking for guidance on the modern ideas about oscillator mechanisms, or for an account of the comparative physiology of clocks will therefore be disappointed.

This is the book's only serious weakness: the unifying thread woven through the fabric of the text is taxonomic rather than physiological. Nevertheless, it is an excellent source work, particularly on photoperiodism, and is to be welcomed for that reason alone. In addition, it provides a much more general textbook on chronobiology than its narrow title implies, a paradigm for the subject as a whole, and in that respect is a considerable advance on any of its rivals with more pretentious titles.

John Brady is Reader in Insect Behaviour in the Department of Zoology and Applied Entomology at Imperial College, London, UK.

announcements

Awards

Royal Society Medals:

A Royal Medal to **J. W. Cornforth**, University of Sussex, for his fundamental contribution to our knowledge of the biosynthesis of steroids.

A Royal Medal to **J. L. Gowans**, University of Oxford and Medical Research Council Cellular Immunology Unit, for his distinguished research in the field of immunology, especially as regards the recirculation and immunological role of lymphocytes.

A Royal Medal to **A. Walsh**, Division of chemical physics, Commonwealth Scientific and Industrial Research Organization, Australia, for his distinguished contributions to emission and infra-red spectroscopy and his origination of the atomic absorption method of quantitative analysis.

The Copley Medal to **Dorothy M. C. Hodgkin**, University of Oxford, for her outstanding work on the structure of complex molecules, particularly penicillin, vitamin B₁₂ and insulin.

The Rumford Medal to **I. Prigogine**, professor and director of the Free University of Brussels, for his distinguished contributions to the theory of irreversible thermodynamics

The Davy Medal to **R. E. Richards**, Merton College, Oxford, for his outstanding contributions to nuclear magnetic resonance spectroscopy and its application to chemical and biological problems.

The Darwin Medal to **Charlotte Auerbach**, University of Edinburgh, for her discovery of and continuing work on chemical mutagenesis

The Sylvester Medal to **D. G. Kendall**, University of Cambridge, for his many distinguished contributions to probability theory and its applications.

The Hughes Medal to **S. W. Hawking**, University of Cambridge, for his distinguished contributions to the application of general relativity to astrophysics, especially to the behaviour of highly condensed matter.

Physics

FULLER, Everett G., and HAYWARD, Evans (edited by). *Photonuclear Reactions* (Benchmark Papers in Nuclear Physics/2). Pp.xviii+426. ISBN-0-470-15142-0. (Stroudsburg, Pennsylvania: Dowden, Hutchinson and Ross, Inc., 1976. Distributed by Halsted Press, a Division of John Wiley and Sons, Inc., New York and London.) \$38; £21.

KILLEEN, John. *Controlled Fusion*. (Methods in Computational Physics: Advances in Research and Applications, Vol. 16.) Pp.xiii+450. ISBN-0-12-460816-7. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) \$47; £27.25.

KESSLER, Joachim. *Polarized Electrons* (Texts and Monographs in Physics). Pp.ix+223. ISBN-3-540-07678-6. (Berlin and New York: Springer-Verlag, 1976) DM 59.80; \$24.60.

LANDOLT-BÖRNSTEIN, Numerical Data and Functional Relationships in Science and Technology/Zahlenwerte und Funktionen aus Naturwissenschaften und Technik. New Series/Neue Serie. Editor-in-Chief. K. H. Hellwege. Group 2: Atomic and Molecular Physics/Atom- und Molekularphysik. Vol. 7. Structure Data of Free Polyatomic Molecules/Strukturdaten freier Mehratomiger Moleküle. By J. H. Callomon, E. Hirota, K. Kuchitsu, W. J. Lafferty, A. G. Maki and C. S. Pote. With the assistance of I. Buck and S. Starck. Edited by K. H. Hellwege and A. M. Hellwege. Pp.vii+395. ISBN-3-540-07577-1. (Berlin and New York: Springer-Verlag, 1976) DM 360; \$147.60.

LANDOLT-BÖRNSTEIN, Numerical Data and Functional Relationships in Science and Technology/Zahlenwerte und Funktionen aus Naturwissenschaften und Technik. New Series/Neue Serie. Editor-in-Chief. K. H. Hellwege. Group 2: Atomic and Molecular Physics/Atom- und Molekularphysik. Vol. 8 (Supplement to Volume 7/Ergänzung zu Band 7. Magnetic Properties of Coordination and Organometallic Transition Metal Compounds/Magnetische Eigenschaften der Koordinations- und Metallorganischen Verbindungen der Übergangselemente, Ergänzungsband 1 (1964-1968). Editors: K. H. Hellwege and A. M. Hellwege. Pp.xviii+1163. ISBN-3-540-07441-4. (Berlin and New York: Springer-Verlag, 1976.) DM 1100; \$451.

MEHRING, M. *High Resolution NMR Spectroscopy in Solids*. (NMR: Basic Principles and Progress/Grundlagen und Fortschritte, Vol. 11.) Pp.xi+246. ISBN-3-540-07704-9. (Berlin and New York: Springer-Verlag, 1976) DM 68; \$27.90.

Chemistry

FULLER, C. W. (edited by). *Annual Report on Analytical Atomic Spectroscopy: Reviewing 1975*, Vol. 5. Pp.viii+267. ISBN-0-85186-757-X. (London: The Chemical Society, 1976.) £15; \$33.75.

HEILBRONNER, Edgar, and BOCK, Hans. *The HMO Model and its Application*. Vol. 2. *Problems with Solutions*. Translated by William Martin and Anthony J. Rackstraw. Pp.viii+449. ISBN-0-471-01473-7. (London and New York: Wiley-Interscience, John Wiley and Sons; Weinheim: Verlag Chemie, GmbH, 1976.) £15; \$33.00.

HEILBRONNER, Edgar, and BOCK, Hans. *The HMO Model and its Application*. Vol. 3. *Tables of Huckel Molecular Orbitals*. Translated by William Martin and Anthony J. Rackstraw. Pp.190. ISBN-0-471-01474-5. (London and New York: John Wiley and Sons, Weinheim: Verlag Chemie, GmbH, 1976.) £9; \$18.

KEITH, Lawrence H. (edited by). *Identification and Analysis of Organic Pollutants in Water*. Pp.x+718. ISBN-0-250-40131-2. (Ann Arbor, Michigan: Ann Arbor Science Publishers, Inc.; Chichester: John Wiley and Sons, Ltd., 1976) \$30.25; £17.90.

PEARSON, Ralph G. *Symmetry Rules for Chemical Reactions: Orbital Topology and Elementary Processes*. Pp.ix+548. ISBN-0-471-01495-8. (New York and London: Wiley-Interscience, John Wiley and Sons, 1976.) \$31; £17.50.

Technology

BLASCHKE, W. S., and MCGILL, J. *The Control of Industrial Processes by Digital Techniques: The Organization, Design and Construction of Digital Control Systems*. Pp.viii+185. ISBN-0-444-41493-2. (Amsterdam, Oxford and New York: Elsevier Scientific Publishing Company, 1976.) Dfl. 77; \$29.75.

EVAN-IWANOWSKI, R. M. *Resonance Oscillations in Mechanical Systems*. Pp.xi+292. ISBN-0-444-41474-6. (Amsterdam, Oxford and New York: Elsevier Scientific Publishing Company, 1976.) Dfl. 77; \$29.75.

FLOWERS, T. H. *Introduction to Exchange Systems*. Pp.xvii+326. ISBN-0-471-01865-1. (London and New York: Wiley-Interscience, John Wiley and Sons, 1976.) £13; \$26.

GOULARD, R. (edited by). *Combustion Measurements: Modern Techniques and Instrumentation*. (A Project Squid Workshop) Pp.xii+483. ISBN-0-12-294150-0. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers; Washington and London: Hemisphere Publishing Corporation, 1976.) \$34.50; £21.05.

MADDIN, Robert (editor-in-chief). *Challenges and Opportunities in Materials Science and Engineering*. (Anniversary volume of *Materials Science and Engineering*.) Pp.vi+264. (Lausanne: Elsevier Sequoia, S. A., 1976.)

MEDELSSOHN, K. (edited by). *Proceedings of the Sixth International Cryogenic Engineering Conference*, Grenoble, 11-14 May 1976. (ICEC, 6) Pp.827. ISBN-0-902852-58-2. (Guildford: IPC Science and Technology Press, Ltd., 1976.) £29.

McDOUGALL, Angus. *Fuel Cells* (Energy Alternatives Series) Pp.xii+147. ISBN-333-18408-4. (London and Basingstoke: The Macmillan Press, Ltd., 1976) Hard cover £7.95; Paper cover £2.95.

PALMER, Andrew C. *Structural Mechanics* (Oxford Engineering Science Texts.) Pp.x+218. ISBN-0-19-856128-8. (Oxford: Clarendon Press; London: Oxford University Press, 1976) Paper £3.50 net; Boards £7 net.

ROBERTSON, J. Craig. *A Guide to Radiation Protection*. Pp.86. ISBN-333-19278-8. (London and Basingstoke: The Macmillan Press, Ltd., 1976.) £4.95.

ROBERTSON, Angus (edited by). *Video Yearbook 1977*. Pp.286. ISBN-0-85642-064-6. (Poole: Dolphin Press, an imprint of Blandford Press, 1976) £4.75.

RUSSELL, Clifford S., and VAUGHAN, William J. *Steel Production: Processes, Products, and Residuals*. Pp.xx+328. ISBN-0-8018-1824-9. (Baltimore and London: The Johns Hopkins University Press, 1976. Published for Resources for the Future.) £12.40.

SZEKELY, Julian, EVANS, James W., and SOHN, Hong Yong. *Gas-Solid Reactions*. Pp.xiii+400. ISBN-0-12-680850-3. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) \$39.50, £24.10.

Earth sciences

GOLDBERG, Edward D. *Strategies for Marine Pollution Monitoring*. Pp.x+310. ISBN-0-471-31070-0. (New York and London: Wiley-Interscience, John Wiley and Sons, 1976.) \$27.50; £16.50.

Biological sciences

ANDERSON, J. M., and MADFADYEN, A. (edited by). *The Role of Terrestrial and Aquatic Organisms in Decomposition Processes* (The 17th Symposium of The British Ecological Society, 15-18 April 1975.) Pp.xi+474. ISBN-0-632-00018-X. (Oxford and London: Blackwell Scientific Publications, 1976.) £14.

BAKER, Joseph T., and MURPHY, Vreni. *Handbook of Marine Science* Vol. 1: *Compounds from Marine Organisms*. Pp.228. ISBN-0-87819-388-X. (Cleveland, Ohio: CRC Press, Inc., 1976.) \$29.95.

BALTIMORE, David, HUANG, Alice S., and FOX, C. Fred (edited by). *Animal Virology* (ICB-UCLA Symposium on Molecular and Cellular Biology, Vol. IV, 1976.) Pp.xi+824. ISBN-0-12077350-3. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) \$29.50; £18.

BANKS, P., BARTLEY, W., and BIRT, L. M. *The Biochemistry of the Tissues*. Second edition. Pp.xv+493. ISBN-0-471-05471-2. (London and New York: John Wiley and Sons, 1976.) Cloth £14.50; \$30. Paper £6.26; \$13.50.

BROWN, Leslie. *Eagles of the World*. Pp.224. ISBN-0-7153-72696. (Newton Abbot and London: David and Charles, 1976.) £4.95.

BROWN, Leslie. *Birds of Prey: Their Biology and Ecology*. Pp.256. ISBN-0-600-31306-9. (London and New York: Hamlyn Publishing Group, Ltd., 1976.) £4.50.

CAPUTO, A. (edited by). *Biological Basis of Clinical Effect of Bleomycin*. (Progress in Biochemical Pharmacology, Vol. 11.) Pp.x+230. ISBN-3-8055-2338-6. (Basel, London and New York: S. Karger, 1976.) Sfr./DM 127.

CHAPMAN, V. J. *Coastal Vegetation* Second edition. (Pergamon International Library of Science, Technology, Engineering and Social Studies.) Pp.viii+292. ISBN-0-08-020896-7. (Oxford and New York: Pergamon Press, 1976.) Hard case £8.75, Flexicover £4.75.

History of science

BRIEGER, Gert H. (edited by). *Theory and Practice in American Medicine: Historical Studies from the Journal of the History of Medicine and Allied Sciences*. Pp.xv+272. (New York: Science History Publications, a Division of Neale Watson Academic Publications, Inc., 1976.) Cloth \$12, Paper \$4.95.

COLLARD, Patrick. *The Development of Microbiology*. Pp.201. ISBN-0-521-21177-8. (Cambridge and London: Cambridge University Press, 1976.) £6.50.

COPERNICUS. *On the Revolutions of the Heavenly Spheres*. A New Translation from the Latin with an introduction and notes by A. M. Duncan. Pp.328. ISBN-0-7153-6927-X. (Newton Abbot and London: David and Charles; New York: Barnes and Noble Books, a Division of Harper and Row, Publishers, 1976.) £12.50.

GIFFORD, Jr., George E. (edited by). *Physician Signers of the Declaration of Independence*. Pp.163. ISBN-0-88202-159-1. (New York: Science History Publications, a Division of Neale Watson Academic Publications, Inc., 1976) \$10.

KANGRO, Hans. *Early History of Planck's Radiation Law*. Pp.xvii+282. ISBN-0-85066-063-7. (London: Taylor and Francis, Ltd., 1976.) £25.

McCORMACH, Russell (edited by). *Historical Studies in the Physical Sciences*. Seventh Annual Volume. Pp.xciv+489. ISBN-0-691-08169-7. (Princeton, NJ: Princeton University Press, 1976.) £19.80.

Anthropology

BAKER, Paul T., and LITTLE, Michael A. (edited by). *Man in the Andes: a Multidisciplinary Study of High-Altitude Quechua*. (US/IBP Synthesis Series 1.) Pp.xx+482. ISBN-0-87933-228-X. (Stroudsburg, Pennsylvania: Dowden, Hutchinson and Ross, Inc., 1976. Distributed by Halsted Press, a Division of John Wiley and Sons, Inc., New York and London.) £18; \$30.

Psychology

BARBER, T. X. *Pitfalls in Human Research: Ten Pivotal Points*. (Pergamon General Psychology Series.) Pp.vii+117. ISBN-0-08-020935-1. (Oxford and New York: Pergamon Press, 1976.) \$6.95.

JUNG, C. G. *Analytical Psychology: Its Theory and Practice*. (The Tavistock Lectures.) Pp.xvi+224. ISBN-0-7100-8414-5. (London and Henley: Routledge and Kegan Paul, Ltd., 1976.) Paperback £1.95.

LIPSITT, Lewis P. (edited by). *Developmental Psychobiology: The Significance of Infancy*. Pp.x+143. ISBN-0-470-15127-7. (Hillsdale, NJ: Lawrence Erlbaum Associates, Publishers, 1976. Distributed by Halsted Press, a Division of John Wiley and Sons, New York and London.) \$12.65, £7.65.

MEDLIN, Douglas L., ROBERTS, William A., and DAVIS, Roger T. (edited by). *Processes of Animal Memory*. Pp.xi+267. ISBN-0-470-15189-7. (Hillsdale, NJ: Lawrence Erlbaum Associates, Publishers, 1976. Distributed by the Halsted Press Division of John Wiley and Sons, New York and London.) \$19, £11.50.

NORMAN, Donald A. *Memory and Attention: An Introduction to Human Information Processing*. (Series in Psychology.) Second edition. Pp.xlii+262. ISBN-0-471-65136-2. (New York and London: John Wiley and Sons, Inc., 1976.)

PORGES, Stephen W., and COLES, Michael G. H. (edited by). *Psychophysiology* (Benchmark Papers in Animal Behavior/6.) Pp.xv+366. ISBN-0-470-15136-6. (Stroudsburg, Pennsylvania: Dowden, Hutchinson and Ross, Inc., 1976. Distributed by Halsted Press, a Division of John Wiley and Sons, Inc., New York and London.) \$32; £17.75.

Sociology

BLACK, Donald. *The Behavior of Law*. Pp.xi+175. ISBN-0-12-102650-7. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) \$12.50; £7.60.

CHIROI, Daniel. *Social Change in a Peripheral Society: The Creation of a Balkan Colony*. (Studies in Social Discontinuity.) Pp.xvii+179. ISBN-0-12-173150-2. (New York and London: Academic Press, a Subsidiary of Harcourt Brace Jovanovich, Publishers, 1976.) \$12.50, £7.25.

KORNITZER, Margaret. *Adoption*. Pp.186. Fifth edition. ISBN-0-370-10059-X. (London: Putnam and Company, 1976.) Hardback £4.95, Paperback £3.50.

McKEOWN, Thomas. *The Modern Rise of Population*. Pp.168. ISBN-0-7131-5867-0. (London: Edward Arnold (Publishers), Ltd., 1976) £7.95.

ROSE, Hilary, and ROSE, Steven. *The Radicalization of Science: Ideology of the Natural Sciences*. (Critical Social Studies.) Pp.xxvi+205. ISBN-0-333-21141-3. (London and Basingstoke: The Macmillan Press, Ltd., 1976.) Hard cover £10; Paper cover £3.95.

ROSE, Hilary, and ROSE, Steven (edited by). *The Political Ecology of Science: Ideology of the Natural Sciences*. (Critical Social Studies.) Pp.xxvi+218. ISBN-0-333-21139-1. (London and Basingstoke: The Macmillan Press, Ltd., 1976.) Hard cover £10, Paper cover £3.95.

Geography

OEHSER, Paul H. (compiled and edited by). *Research Reports*. (Abstracts and reviews of research and exploration authorized under grants from the National Geographic Society during the year 1968.) Pp.x+527. ISBN-087044-136-1. (Washington, DC: National Geographic Society, 1976.) \$5.

General

BUSVINE, J. R. *Insects, Hygiene and History*. (London: The Athlone Press, University of London, 1976. Distributed by Tiptree Book Services, Ltd., Tiptree, Essex; Humanities Press, Inc., New Jersey.) £6.95.

FARSON, Daniel (compiled by). *In Praise of Dogs*. Pp.118. (London: George G. Harrap and Co., Ltd., 1976) £3.95 net.

GOLDSTEIN-JACKSON, Kevin. *Experiments With Everyday Objects*. Pp.187. ISBN-0-285-62245-5. (London: Souvenir Press, Ltd., 1976) £3.

ROSZAK, Theodore. *Unfinished Animal: The Aquarian Frontier and the Evolution of Consciousness*. Pp.ix+271. ISBN-0-571-11014-2. (London: Faber and Faber, Ltd., 1976.) £2.95.

nature

December 9, 1976

Some seasonal greetings

To our leader writer:

May all your issues be central ones; may every corrective measure be at once too little and too much.

To book blurb writers:

May all your wares continue to be of interest to highly qualified specialists, students and the layman alike.

To those eminences who require their secretary to type after their name MA, PhD, ScD, FRIC, FInstP, FICE, CEng, FRSEdin:

May you excuse the modesty of our response.

To Hills Road, Cambridge:

May your access to our columns be as easy as everyone else in the world assumes it is.

To all our London subscribers:

May we never again send you *Nursing Times* instead of *Nature*. Think of what the poor nurses had to wade through.

To all directors of big government laboratories:

May you never again need to be thanked for granting permission to your staff to publish.

To all those whose notepaper is headed:

US Department of Health, Education and Welfare,
Federal Ventures Office,
Bureau of Diseases,
Common Cold Eradication Program,
Viral Infection Project,
University of South Chicago,
Western Campus,
Emily Smoot Building,
Department of Biochemistry,
Sub-department of Sneeze Research,
Room 3581

May you get a box number.

To all authors of rejected papers:

Even though you are 'naturally disappointed' by our decision, may you maintain your custom of 'not being in the habit of writing to complain'.

To all those who telephone us and find us unavailable:

May you ring us again; we won't ring you.

To all our readers:

May your grumbles find their way to us; we may not be on the same grapevine as you.

To a scientific jet-setter:

May you look on the messages board at Heathrow airport. We don't send letters to you at your department any more.

To the editors of new journals:

May there always be interdisciplinary subjects crying out for a new journal dedicated to rapid dissemination of results; may you find a goodly number of Nobel Laureates for your editorial board.

To our referees:

May we never again send an expert on tadpoles a paper on general relativity. And if we do may it never take a month for him to let us know.

To Tom Jukes and Kenneth Mellanby:

May you find issues for your columns as black and white as we make your faces.

To our printers:

May we come to some agreement on the spelling of millennium.

To Professor J. L. Jinks:

May we never again call you Professor J. L. Links.

To our sub-editors:

May you remember the difference between partly and partially, and between compared with and compared to; may you put b.p. but bc.

To readers of News and Views:

May you find your own work described therein—and not in slighting tones either.

To our authors:

May you put your conclusion in your first paragraph. After that can come the introduction. The middle bit then goes at the end.

The Flowers Report: opportunities missed

Dr R. H. Mole, Director of the MRC Radiobiology Unit at Harwell, offers some personal reflections on the recent nuclear power report of the Royal Commission on Environmental Pollution

THE Report's main conclusion is that there are substantial environmental objections to a nuclear power programme on the scale envisaged (paragraph 534) and that we should not rely for energy supply on a process that produces such a hazardous substance as plutonium unless there is no reasonable alternative (paragraph 535). In an earlier paragraph (186), the conclusion is much more categorical: although aware of the advantages that nuclear power offers the Commission did not think that these outweigh the risks described. Routine electricity production by nuclear means, however, appears to be regarded as unobjectionable.

It is necessary to consider important omissions from the Report, so important as to appear to warrant asking whether these conclusions are justified.

The human cost

The routine environmental effects of nuclear power may well be much less damaging than those of fossil fuelled power stations... The discharges of radioactivity from nuclear stations, both to air and water, are radiographically insignificant and there are no discharges of offensive gases or particulates. (191).

... the aspects of nuclear development which cause most dissension tend to be those that relate not to normal operation but to the possibility of abnormal events such as accidents at nuclear installations or malevolent acts against them. (10).

Although the Report says that the Commission "should be concerned not so much with the individual risk as with the total effect of possible accidents" (173) this total effect is never considered. The human cost of nuclear power is considered and enumerated only in relation to single examples of what were said to be very unlikely events, an exceptional release of radioactivity into the sea at Windscale (139) or into the atmosphere from a serious reactor accident (263-268). There is nothing in the Report to show that the Commission considered or enumerated the total casualty rate from reactor malfunctions and small accidents which will occur much more frequently than exceptional severe accidents, or even from the routine operation of power reactors without malfunction. Is it a mistake to conclude that, when the Commission concentrated on exceptional occurrences, it did not know whether it had addressed itself to the real problem of nuclear safety or only to a minor aspect of it?

In relation to the possibility of terrorist activities the Commission con-

tented itself with stressing that purloining enough plutonium to make a crude bomb is bound to happen sooner or later but did not attempt to deduce the likely or possible consequences in terms of numbers of casualties. Thus on this question the Royal Commission with all its expertise and resources has added nothing to what has been said repeatedly over the past few years by the ordinary journalist.

Energy Strategy

Chapter IX on Energy Strategy considers energy needs and alternative means of satisfying those needs but nowhere considers the human costs of getting energy by any means, except to take for granted that nuclear power is basically hazardous. Much of the Report's anxiety seems to be based on "the assumed necessity of securing steadily increasing energy supplies" (197) as illustrated in Table 14. But no facts are provided to enable the reader to consider what methods of supplying energy might be the safest to the population and the least damaging to the environment if there was no need to increase energy supplies at all. Chapter VI is said to relate nuclear and non-nuclear hazards (16) but it does not do this for alternative means of getting energy.

The Commission's failure to compare the human costs of alternative sources of energy and to consider the total effect of possible accidents can make its anxieties about exceptional serious accidents seem wholly unbalanced. This can be illustrated as follows. The current death rate from accidents amongst employees of the National Coal Board is in round terms 50-60 per year. The number of cancer deaths from a particular example of failure of containment of Caesium-137 at Windscale is given as perhaps fifty in total (spread out over many years). Such an event is said not to be at all likely and its consequences are used to illustrate the need for the strictest containment of radioactive wastes for very long periods (139), as if the number of casualties was something out of the ordinary and perhaps unacceptable to the Commission.

The large radioactivity release considered as an exceptional but very serious event is of 10^7 Ci Iodine-131, 10^6 Ci Caesium-137 and so on, and would give 110-350 deaths from cancer (263-268). This is the same as the number of accidental deaths in coal production in UK over a 2-6 year period

at the current annual rate. The probability of release of 10^7 Ci Iodine-131 is 10^{-7} per reactor year (the Report's Figure 15). One hundred reactors each of 1,000 MW would produce twice as much electricity as the whole of that generated by all means in UK in 1975 (462, 468), and the probability of release of 10^7 Ci Iodine-131 would then be once every 100,000 years. On this count alone nuclear power would appear to be more than 10,000 times safer than coal power.

Such a comparison is obviously inadequate since it is between a most exceptional event and a routine annual occurrence. It shows very clearly how misleading it may be to concentrate on exceptional events with large consequences and to ignore much commoner events each with relatively small consequences. Differences in emphasis on these contrasting sources of risk were in fact noted by the Royal Commission as the reason for inconsistencies in evidence on the policy for siting reactors (296), but the Commission seems to have failed to appreciate the significance of the matter for itself.

Consistency in assessing the acceptability of risk

The Royal Commission emphasised the need for a body with statutory responsibility for endorsing the basic standards for radiological protection on the national behalf (223). Such a body must be clearly independent of any interests promoting developments involving radioactivity, it is agreed, but the conclusion can be questioned that "in view of the importance of the issues it should be a body constituted specifically for radiological protection" (223). Whatever the history of how the basic standards were chosen, they are expressed in terms of tissue dose and, therefore, can be specifically related to risk.

Technically this relation must be as exact as current scientific understanding will allow, but "the importance of the issues" at the present time is not so much the degree of technical accuracy as the acceptability of the corresponding risk. This cannot be wholly determined by any body specifically constituted only for radiological protection, as that phrase would normally be understood, because acceptability is not a radiological matter. The non-technical essence of the choice of basic standard is to set the corresponding level of risk at that point on the scale of risk which makes it acceptable in the light of all other sources of everyday risk in work and generally.

The Royal Commission recognised that the collective action of involved government departments was inad-

equate for providing advice on energy strategy (515) and recommended the need for an independent high-level advisory body on the subject (535). All the more reason for recognising the need for a central body to consider and report publicly on the level of acceptability of risk in relation to the various means by which the great variety of national needs could be satisfied, energy supply being but one of these. Consistency in assessing acceptability of risk is required not only within the energy field but also between the energy field and other major national activities not excluding the practice of medicine.

For example, at the present time roughly as much Iodine-131 is administered to patients, and from them is released into the environment each year, as would be released on average per year over the 100,000-year period within which one most exceptional release of 10^7 -Ci Iodine-131 might be expected from a hundred nuclear reactors routinely generating electricity.

Public reaction to risks

A major factor in the Royal Commission's approach, although not made wholly explicit, is expressed clearly enough in the Report: risks of events that affect people individually or in small numbers, it says, "are fairly readily accepted as inevitable", but events "that cause death or injury to many people at one time . . . have, in proportion to the numbers affected, a much greater impact in creating public concern" (172 and see 270).

The Commission, in emphasising so strongly the exceptional event and accepting almost without question the safety of routine discharges of radioactivity into the environment, seems to have adopted the same attitude. Even if the members of the Royal Commission regarded themselves as in some sense representatives of the public or trustees of the national interest, there seems no reason why they should accept these public attitudes as given and unchangeable and appropriate for themselves. It was surely within their remit to attempt to change public attitudes by explanation and reason. This would certainly have to be a function of a central body to consider acceptability of risk, as suggested above, if it was to succeed in providing consistent guidelines on emotive subjects.

Responsibilities and experts

The Royal Commission found it difficult to obtain independent but expert advice "since the acknowledged experts are often themselves involved in the related developments" (163). So far as assessing the effect of pollutants, including radioactivity, "we can do no better than require that the agencies concerned are expert, open and in-

dependent, and such as to ensure that necessary research is undertaken and that assessments are appropriately revised in the light of new knowledge. The requirement reflects on organisational arrangements" which are required (188).

The International Commission on Radiological Protection (ICRP) "is only as good as its members, and it is vitally important that these should continue to be appointed independently of the approval of their national governments and purely on the basis of their professional standing amongst their scientific peers . . . We hope that there will continue to be a strong British representation on the ICRP . . ." (203).

A main problem, however, with the Commission's recommendations for systematising responsibilities is that they will still further reduce the possibilities of finding informed and at the same time independent experts, that is independent of interested organisations.

Bodies with statutory responsibilities as proposed by the Commission, such as the strengthened NRPB, the Nuclear Waste Management Committee, the Nuclear Waste Disposal Corporation, the strengthened Health and Safety Executive (531) and HMPI (527), will clearly attract to themselves the best experts they can find. Any British members of ICRP will inevitably be found to belong to NRPB as, even now, three out of four current British members of ICRP do. Each such body will get financial support from government sources. Are they in the least likely to criticise each other publicly as the Royal Commission said they should be free to do? If an organisation has statutory responsibilities it must have a "party line" to which its employees conform. Even if, like NRPB at present, it is a national centre for advice without statutory responsibilities, it must ensure consistency in the advice it gives. Is this conducive to criticism from within of scientific or technological bases of action?

What the Royal Commission quite rightly seemed to desire was to maximise the possibilities for what might be called informed assent and dissent. This requires not only publicly available information but the existence of individuals who are not beholden to organisations with statutory responsibilities and who are technically educated and intellectually free to pursue argument and the advance of knowledge without the confinement of terms of reference or administrative boundaries.

Is there a big enough reservoir of such individuals for national needs? It wouldn't seem so for radiobiologists if major reports in Britain, like the Royal Commission's, and in the USA, like the

Rasmussen Report on Reactor Safety, were each radiobiologically defective, and the same reasoning can be applied to any other scientific field covered by the Royal Commission Report. The only way of remedying this sort of deficiency is to see that universities and polytechnics pay sufficient attention to the field of knowledge and that research councils play their part.

Research priorities

The Royal Commission regarded the arrangements for initiation and co-ordination of research as of the greatest importance but in no case was the priority of research discussed in relation to the quantitative importance of the subject matter as it relates to risk. Research could well be justified if a more than negligible risk is to be assessed but, if routine nuclear power is already known to be unobjectionable as suggested by the Commission, would research on its hazards be needed? It could hardly be justified merely by legislative requirements for annual surveys of discharges of radioactivity (251).

Debate and accessibility of fact

In its last few paragraphs the Royal Commission Report quite rightly stressed the importance of public understanding of the long term issues of unusual range and difficulty raised by nuclear development (521), and the need for open and deliberate weighing of risks and costs of embarking on a major nuclear programme against those of not doing so (522). But such an open political process will generate only hot air and useless emotion unless there is an agreed basis of technological fact from which to start. The scientific convention is to provide a reference for every possibly arguable fact, and this systematic buttressing by checkable publications is something the dyed-in-the-wool scientific reader rather sadly misses. The enquirer cannot make the checks he may desire: for example, the source of only ten of 25 Figures and three of 14 Tables is acknowledged, and even then a specific reference is provided for only four of the 13 sources acknowledged. Perhaps a Royal Commission Report, especially if it deals with complex issues, is not a suitable place for a comprehensive reference list, but it must be a retreat from established scientific methodology if a Report of a Commission on highly technical questions is without adequate references because then its authority is simply the eminence of its individual members. This is a special problem in the present case, because many readers of different backgrounds have recognised serious defects in the Report.

For instance, the Royal Commission

was concerned that insufficient research and attention had been given to atmospheric pollution by radioactivity (234), yet there is no evidence that the Commission knew of the more than 100 scientific papers on this subject published from the Environmental Sciences and Medical Division of AERE.

Conclusions

The Report of the Royal Commission on Environmental Pollution fails to provide (i) any evaluation of the relative level of risk of nuclear power from accidents and from normal operations, (ii) any corresponding evaluation of

risk from other means of energy supply, (iii) any recommendation for a means of considering the level of risk in relation to acceptability on the national behalf.

Without (i) it would seem that the Royal Commission cannot know whether or not, in its emphasis on exceptional occurrences, it has tackled the real problem. Without (ii) its examination of Energy Strategy is woefully inadequate. Without (iii) its recommendation for a strongly based national body to consider radiological protection leaves that body with no standards by which to take decisions.

The Report concluded that plutonium must not be produced on a large scale until it is demonstrated that the plutonium can be taken care of safely. This is bound to be generally agreed. But safety is an open-ended concept and it must be a matter of judgment to decide whether what is known does or does not amount to the demonstration of a sufficient degree of safety. No criteria are provided by which such a judgment could be made.

Without all these, how can there be a deliberate weighing of the risks, costs and advantages of a major nuclear programme? □

Flowers on Flowers

Sir Brian Flowers, who recently stepped down as Chairman of the Royal Commission after 3½ years, made his first public comments on reaction to the nuclear power report when he spoke at the British Nuclear Energy Society last week. Some extracts:

On the disposal of radioactive waste: "I have occasionally been asked what we meant by demonstrating a method beyond reasonable doubt. There appears to be agreement that a full programme of research might take a decade or more, but we argue that in any case we have that time available before becoming irretrievably committed to nuclear power as a major component of our electricity supply. I would suggest that what is needed in addition to a vigorous, systematic research programme is to choose and to set aside as soon as possible at least one specific site for which there is a consensus of geological, hydrological and other relevant opinion that it is acceptable for inaccessible disposal. It need not be the one eventually adopted, but it would provide a fall-back position. This, too, is a problem that exists irrespective of the future of nuclear power."

On alternative energy strategies: "The crucial long-term issues are on the one hand the competition between nuclear energy and coal, and on the other hand between both and renewable resources; and also between high electricity and therefore high heat-waste, on the one hand, and vigorous conservation measures on the other. Whether it is looked at from the industrial or the environmental point of view there is a very strong element of nuclear versus the rest. In these circumstances it is vital that responsible advice to Ministers should be seen to be independent of the major factions in the argument. I believe that it should be a matter of public

concern that this is not at present the case."

On the possible effects of illicit activities: "On this issue, alone amongst all those we studied, we were given very little help by official bodies . . .

" . . . Probably the Government already has all the legal powers it would need under the Anti-Terrorist Acts of 1974 and 1976. Is Mr Eadie [Minister of State at the Department of Energy] saying that the Government has consciously resolved that the use of these powers is acceptable to safeguard the future electrical power industry? And that the changes then implicit for our society will be amply offset by the economic benefits of nuclear power? Perhaps he is, and perhaps he is right; but how are we to know unless we can discuss the matter? The Royal Commission does not know the answers to these questions. It merely considers them important and asks that they be discussed before we develop a reliance on nuclear power. If the Government continues to skulk behind the Official Secrets Act we may not know until it is too late to wish that it were otherwise."

On nuclear weapons proliferation: " . . . Thanks to the vested interests of the nuclear weapons states; thanks to the huge R&D resources already devoted to the development of nuclear power; thanks to the almost universal belief in a continuing abundance of cheap electricity, only recently shown to be a myth by the oil sheiks; thanks to the ensuing lack of attention paid to the need for energy conservation, the exploration of more meaningful long-term energy strategies, and the development of alternative sources; and on the global scale, thanks above all to the lack of any effective population control—it is simply not possible in 1976 to state with the required

degree of certainty that the world need not be dependent on nuclear power beyond the end of this century. A severe lack of energy, and the continued division of the world into rich and poor which some would then envisage, might itself be extremely dangerous, even to the extent of bringing in the very nuclear hazards we were seeking to understand and if possible to lessen."

On the question of developing a commercial fast breeder reactor:

"Judging by experience from other prototype reactors we shall still be learning a great deal from it in five or even ten years' time. In any case, it is now unrealistic to suppose that the first full-scale breeder reactor, the so-called CFR-1, could be started in under three or four years, even given the approval tomorrow. That gives ample time for the nuclear debate to come to a conclusion. I believe one should contemplate building any such reactor on a remote site contiguous with its own recycling plant so that there would be no need, after the first loading, for substantial quantities of plutonium to enter or leave the site. It is hardly likely that the result would justify the adjective 'commercial', but I believe it could be done in an environmentally acceptable fashion provided there is no commitment to an ongoing programme."

"But I see no need for undue speed, even if one believes there is no avoiding fast reactors and the plutonium economy they entail. Thermal reactor development has proved to be within the capacity of the United Kingdom, but only just. Fast reactor development is likely to be beyond our resources. It seems to me essential that if we pursue it at all we should do so on a European basis. I can see no reason for wishing it were otherwise now that we are fully committed to the European Community . . ."

Nature's Christmas issue a year ago carried an article entitled 'Naming the Loch Ness monster'. This year, **Carl Sagan** writes on 'Detection times and number densities of rare mobile organisms: application to Loch Ness'.

If there are any, could there be many?

IN simple collision physics, when one moving object may collide with a number of stationary and dissimilar targets, the mean free time for collision is $t = (n\sigma v)^{-1}$, where n is the number density of stationary targets, σ is the mean collision cross-section and v is the relative velocity (assumed constant). If targets are also moving, a factor of order unity multiplies the denominator of this equation; for example, if all objects have Maxwell-Boltzmann velocity distributions, the multiplier is $2^{1/2}$.

This same equation, slightly modified, can be used to deduce the number density in three dimensions of a distributed rare mobile organism from the mean free time between sightings of this organism by a stationary or moving observer. In this case the collision cross-section $\sigma = \pi r^2$ where r is the target visibility range—the linear distance over which the target is within the resolving power of the observer; or the distance to optical depth unity in the enveloping medium; or the distance to the horizon, whichever is least. When t is measured by a stationary observer, the mean distance between organisms will then be

$$S = 2(3t r^2 v/4)^{1/3} \quad (1)$$

If the total volume in which the organisms are contained is V , the total population of organisms in this volume is

$$N = V/(\pi r^2 vt) \quad (2)$$

These relations assume that the organisms being observed are neither attracted to nor repelled by the observer, and that the observer has chosen a typical locale in the organism's habitat—for example, not in the vicinity of concentrations of predators or prey. Under these circumstances equations (1) and (2) provide expectation values for the mean separations and total numbers of organisms. In the common case that the geometry is two- rather than three-dimensional (as, for example, for land animals and to a significant extent even for birds), n is replaced by N , the column density of organisms, σ is replaced by r , $S = 2(rvt/\pi)^{1/2}$ and $N = A/rvt$, where A is the area of the total habitat.

As a practical application, consider the interesting and controversial set of observations suggesting the presence of large organisms in Loch Ness¹. Sonar and underwater stroboscopic photography in 1975 imply $t \approx 10^4$ to 10^5 s

for some unidentified large animal of characteristic dimensions 10 m. We adopt $t \approx 3 \times 10^4$ s, but bear in mind the impression of the observers that in 1975 the organisms may have been attracted by the observational equipment and therefore that the appropriate t is significantly longer. Because of the turbidity of the loch, $r \approx 10$ m; and a rough estimate of the swimming velocity of the unknown animals is $v \approx 3 \text{ m s}^{-1}$.

Equation (1) then immediately gives $S \approx 0.4$ km, a very large mean separation distance. The total volume of Loch Ness is approximately 10^{16} cm^3 , whereupon, from equation (2), $N \approx 300$. Because of the cube root in equation (1), our estimate of S is reasonably independent of the uncertainty in t . But our uncertainty in estimating the total population is proportional to the uncertainty in our estimate of t . If the targets were indeed attracted to the observing apparatus, then N is less, and a conservative estimate places N between several tens and several hundreds. Curiously, this is just the estimate derived independently from biomass calculations, assuming that the diet of the unknown organisms is exclusively migratory salmon² or exclusively non-migratory prey³. While the agreement of these two quite different sets of calculations—from the waiting time for observation in 1975 and from the biomass of the loch—should not be overstressed, the agreement does tend to support the contention that there is a real population $\approx 10^{2 \pm 1}$ of large organisms

inhabiting Loch Ness.

The negative photographic results for 1976 have been attributed⁴ to the sharply diminished fish population and significant increase in temperature in the loch, connected with the 1976 drought. If the 1976 results were not anomalous, we might deduce $t \geq 10^7$ s, and $N \leq 1$. However, sonar encounters at larger r were recorded in 1976.

The nature of these organisms seems still more uncertain than their existence, but it appears more likely that they are a minor variant of a fairly abundant contemporary taxon than, for example, the only surviving group of aquatic Mesozoic reptiles. The large calculated separation distances in a medium as turbid as Loch Ness suggests that the organisms might be equipped with echo locator organ systems and may communicate at audio frequencies. Hydrophones should be an important adjunct to any continuing study.

Similar calculations of organism spacing and loading density could be made on other planets, were macro-organisms to be discovered there—as, for example, on Mars with the Viking lander imaging system. □

New career for Glomar Explorer?

The National Science Foundation is looking into the possibility of converting the Central Intelligence Agency's Glomar Explorer into a deep sea drilling vessel. Colin Norman reports from Washington.

WHEN it became known in March last year that the Central Intelligence Agency (CIA) had used a vessel called the Glomar Explorer to scoop bits of a sunken Soviet submarine from the bottom of the Pacific, a number of scientists in the United States expressed concern that the affair could jeopardise flourishing Soviet-American cooperation in deep sea research. A particular worry was that the Soviet Union might sever its ties with the deep sea drilling project (DSDP), a highly successful ocean drilling programme which the National Science Foundation was then endeavouring to turn into an international research enterprise. Ironically, however, the DSDP may turn out to be the chief beneficiary of the CIA's salvage operations.

Last week, the National Science Foundation (NSF) announced that it is studying the possibility of converting the Glomar Explorer into a drilling vessel for possible use in the 1980s. NSF officials, and their clients in many earth science laboratories, are hoping that the Glomar Explorer will provide a cut-price way of carrying out drilling projects which are beyond the capabilities of the present DSDP vessel, the Glomar Challenger. Though it is far from certain that the NSF will be able to get the funds to turn the vessel into a research ship, it is the only use for the ship which is now under serious investigation.

The Glomar Explorer was constructed for the CIA by Global Marine Inc (the same company which built and operates the Glomar Challenger, hence some of the worry about Soviet scientific reaction), for a sum reported to be about \$300 million. Though publicly billed as a special seabed mining ship built by Howard Hughes, the reclusive billionaire, it was designed for the specific purpose of salvaging a Soviet submarine which sank in about 1,700 feet of water 750 miles north-west of Hawaii in 1968.

The ship recovered bits of the submarine in June 1974—how much is still a matter of some dispute—and when reports of the operation began leaking to the press nine months later, the CIA suddenly found itself with an almost new vessel for which it could

find no further use.

In the meantime, earth scientists have begun to think about what should follow the present phase of the DSDP. The choice boils down to either dispensing with deep sea drilling entirely or mounting a programme of drilling in presently inaccessible areas such as potential oil-bearing regions, the ocean trenches and under the Arctic sea, a programme which would require a new vessel with greater capabilities than the Glomar Challenger. It would require considerable lifting capacity to handle the long drill strings needed for drilling in ocean trenches, and a thick hull to penetrate the Arctic ice. Moreover, since drilling in the ocean margins entails the risk of striking gas or oil deposits, the vessel would have to be able to handle complex and heavy apparatus to prevent possible blowouts. Construction of such a vessel would probably cost between \$60 and \$70 million, a price tag which probably puts it out of the reach of NSF's strained budget.

But Peter Wilkniss, the NSF project director for the DSDP, noted in an interview last week that "when you look at the requirements, it becomes obvious that the Glomar Explorer is almost ideally suited." It is 618 feet long, compared with 400 feet for the Glomar Challenger, and it is capable of lifting about 2,000 tons—more than 10 times the capacity of the Challenger. Moreover, its more powerful engines and greater stability would probably allow it to work in rougher seas.

It is by no means certain, however, that the vessel could be converted

easily and cheaply from a salvage ship into a deep sea drilling vessel, and thus NSF has authorised Global Marine to conduct a preliminary study, under a \$75,000 contract, of the feasibility of converting and operating the Glomar Explorer. The results of that study should be available early next year. In the meantime, the Scripps Institution of Oceanography, which manages the DSDP under a contract from NSF, is looking at the scientific requirements of an expanded drilling programme.

So far, NSF has not given much thought to arrangements for operating the ship if it does decide to acquire and convert it. But, in view of the potentially high costs of operating the vessel—Wilkniss estimates about \$30,000–40,000 per day, twice that of the Glomar Challenger—there would be obvious advantages in seeking international participation.

In that case, the Glomar Explorer's past associations could pose a problem. Though the Soviet Union did not pull out of the DSDP after the submarine salvage attempt was made known, the operation is said to be a sensitive matter and some ocean researchers privately wonder whether the Soviet Union would participate in a venture for which the Glomar Explorer was a central feature.

It should also be noted that if NSF does decide to follow the present DSDP with a programme of drilling in the ocean trenches and on the continental margins, much of the work would be carried out within the 200-mile economic zones likely to be established as part of a Law of the Sea agreement. That would subject the research to a possible veto by coastal states in whose waters the Glomar Explorer may want to work. □

USA

● The Joint Committee on Atomic Energy, the Congressional body which has reigned supreme over nuclear policy in the United States for nearly three decades, last week suffered a severe, possible fatal public battering. Already weakened by the loss of several key members through retirements and election defeats, and facing concerted attack from senators and congressmen seeking its abolition, the joint committee last week became the target of some well-aimed barbs hurled by Common Cause, an influential lobbying group.

In a lengthy review of the joint committee's activities, Common Cause says it has uncovered numerous examples of "procedural abuse", pro-nuclear bias, and failure to examine important issues. The harsh indictment may turn out to be an important factor in persuading Congress that the time is ripe to carve up the joint committee's responsibilities and divide them among other congressional committees, a move which is already being planned and which would have important implications for nuclear policy.

The joint committee derives much of its immense power from its unique status as the only Congressional committee which handles legislation in both the House and the Senate. Every bill related to nuclear power, no matter where it originates, must be referred to the joint committee, a fact which gives its 18 members a monopoly over nuclear legislation.

Formed shortly after the second world war to oversee the United States's nuclear weapons programme, the joint committee rapidly became one of the most powerful committees in Congress. For more than two decades its authority went largely unchallenged and legislation it approved was virtually guaranteed easy passage through the House and Senate. But, as nuclear power has turned into a controversial issue, the joint committee has attracted increasing fire from nuclear critics. It has been persistently accused of pro-nuclear bias, and in the past couple of years a few other Congressional committees have even begun to invade its turf by holding hearings on nuclear matters. (The joint committee is still the only committee with authority to consider nuclear legislation, however.)

Criticisms of the committee have recently given way to more strident calls for its complete abolition, and the Common Cause blast is no exception. The organisation's report pre-

sents evidence that the joint committee has given short shrift to the concerns of nuclear critics, failed to explore important nuclear issues which raise doubts about nuclear power, refused to take the lead in examining major policy questions—such as nuclear proliferation—and often used its unique Congressional position to rush legislation through both the House and Senate before

relevant studies have been completed.

Common Cause also notes that the committee has persistently voted for increases in nuclear spending, adding more than \$850 million to the budget of the Energy Research and Development Administration (ERDA) in the past three years alone. Those actions, Common Cause claims, can be explained in part by the fact that the committee is "dominated by representatives who have a vested interest in encouraging increased nuclear spending". In the last session of Congress, for example, 12 of the committee's members represented six states which together carried off more than half the funds distributed by ERDA.

The chief recommendation from Common Cause is that the joint committee should be scrapped and its responsibilities transferred to House and Senate committees which have broad authority over all energy research and development matters. The report is likely to give considerable impetus to moves already afoot which would accomplish precisely that objective.

Next month, when Democrats in the House of Representatives meet to consider their political agenda, Representative Jonathan Bingham will propose that the joint committee be scrapped and its responsibilities be consigned to other committees, probably the Science and Technology Committee or the Interior Committee. And a committee reorganisation plan

proposed recently for the Senate would transfer the joint committee's responsibilities for nuclear research and development to an expanded Interior committee, and its authority over nuclear regulation to a new Public Works and Environment committee. The reorganisation plan is expected to be debated by the Senate in January, as one of its first items of business.

● If the Joint Committee on Atomic Energy is scrapped by the new Congress, the nuclear industry in the United States would lose one of its most important political allies just as a number of matters deemed crucial to the industry's long-term interests are coming to a head. Among those issues is whether the United States should press ahead with the liquid metal fast breeder reactor programme, at present the highest priority and most lavishly funded energy research and development effort supported by the federal government.

In that regard, a report published last week by the General Accounting Office (GAO), an investigative agency of the Congress, is unlikely to help the LMFBR's political acceptability. The report estimates that it would cost some \$150,000 million to build the 128 breeder reactors which ERDA is now planning, compared with \$95 million to build coal plants of an equivalent capacity and \$128 million for light water reactors. That level of capital expenditure would be difficult for the electricity industry to raise without federal assistance.

● There has recently been a spirited debate in many countries about how to dispose of commercial nuclear wastes and keep them isolated from the environment for thousands of years. The disposal of nuclear wastes from military programmes in the United States is, however, an even bigger problem. Last week, the Energy Research and Development Administration announced that it hopes to start drilling next year in some 13 states to find suitable sites for commercial repositories. Though no sites have yet been short-listed, ERDA officials said that they hope to have the first repository in operation by 1985, and some six in operation in the 1990s. The total cost of the programme, which will handle some 330,000 cubic feet of material by the year 2000, is reckoned to be \$2,000 million. Under questioning, however, ERDA officials said that the total amount of waste generated by military programmes by 2000 will be about 11 million cubic feet, and the cost of getting rid of it could be as much as \$20,000 million.

Colin Norman

FRANCE

La Soufrière's first victim

Fierce disagreement characterised the debate amongst French scientists about La Soufrière, the volcano in Guadeloupe in the French Antilles. A report from La Recherche:

WHEN La Soufrière started to grumble in July 1975 the memory of the 30,000 victims who perished in the cloud of burning ash thrown out by Pelée Mountain in Martinique in 1902 made the question of evacuation particularly important. Some 72,000 people were living at the foot of La Soufrière, which is one of a group of volcanoes in the Caribbean island arc.

Its activity has been characterised by its andesitic nature, the relative viscosity of its magma, the long periods of calm between eruptions and particularly by the explosive nature that its eruptions can have. Although known eruptions (1797, 1836 and 1956) had produced only a slight rain of volcanic dust and released some steam, the authorities eventually did evacuate the local population as a preventative measure. But after a period of intense activity in July and August, the volcano seemed to quieten down again. Things should then have returned to normal; in fact the trouble had only just begun.

On October 27, the board of the Teaching and Research Unit (UER) of the Institute of Physics of the Globe (IPG) met to discuss with the Director of the Institute, M Allegre, the case of Haroun Tazieff, the famous French volcanologist. Allegre informed the board that he had decided to dismiss Tazieff (63) from his post as director of vulcanology at the IPG. Tazieff, he explained, had refused to guarantee that he would fulfil the commitments of the post, after being asked to do so several times and in particular at the beginning and end of August. That followed criticisms of Tazieff for going off to hunt for three Britons lost in the Andean Cordillera when 72,000 French people could have been in danger.

Although no vote was taken at the meeting those present unanimously approved the measure. As the IPG does not come under the administrative jurisdiction of the National Centre for Scientific Research (CNRS), Tazieff continued as a research director at CNRS; his team was anyway in the process of moving to Gif sur Yvette outside Paris to be on CNRS premises. The break with the IPG was complete, though, because Tazieff had no desire to remain any longer on its staff.

The episode marked the culmination of an unfortunate conflict between French scientists which had for several months taken precedence over the real problems confronting the people of Guadeloupe, already faced with considerable political, social and economic difficulties. The UER has given its official reasons for the dismissal of Tazieff, but some believe it may be the result of a quarrel which has been exacerbated by a series of petty disagreements over the differing interpretations of the phenomena observed on the volcano itself.

Tazieff's own somewhat strong words, which the press willingly echoed, started the quarrel and made it all the more bitter as time went on. In *Le Monde* (September 5) he declared that he "could expose the faulty reasoning which has led certain scientists not competent in vulcanology to put forward mistaken prognostications, which the volcano itself has proved wrong in the past six weeks, but I will only do so in a scientific journal." Five days later, there were even stronger words in the weekly *L'Aurore*: "Those who blocked my way are incompetent," he declared. "They are all perfectly competent in their own fields, but they should not try to interfere in vulcanology. If you have trouble with your liver you do not consult an ophthalmologist."

The confrontation deepened on the scientific plane. From July 1975 La Soufrière manifested an increasing number of the phenomena which have now died down again: a seismic shock in March, the appearance of new fractures, underground phreatic eruptions (in July), exceptional seismicity, stronger and more frequent eruptions (in August). Over this period, the number of seismic shocks registered rose from 30 in July 1975 to 209 in November, 607 in March this year, 1,220 in July and, in August, almost 6,000 tremors.

The scientific community agreed on these facts, but there was no unity about the diagnosis. On the one side, Professor Robert Brousse declared that he could no longer rule out the possibility of an explosive phase which could come very suddenly. John Tomblin of the University of Trinidad supported this viewpoint. On the other hand, Tazieff was more reassuring, saying that there was no need to fear a rapid development, and that the only risks for September were from the underground eruptions which endangered only the immediate vicinity

La Soufrière

of the volcano. "Any major eruption," he added, "will be preceded by warning signals for about a week."

On August 15, after a strong tremor of magnitude 4.6 shook Guadeloupe, the political authorities organised a massive evacuation of the population. Even though Allegre wished to hold a middle view between the two extremes, in effect he confirmed the alarmist views of Brousse when he sacked Tazieff, describing his statements as unscientific.

A committee of international experts met in Paris in the middle of last month, brought together by the CNRS to give its opinion on the surveillance programme for the volcano, its organisation, and the results obtained. During these meetings, members have been listening to the many French and international scientists who have been involved with La Soufrière.

It appears from the discussions that there is no danger in the short term of any sudden explosive phenomenon, and that all changes in the behaviour of the volcano should be easily registered by the modern instruments available. It is essential, the committee has noted, that the equipment at La Soufrière should be improved and reinforced. This means that the number of seismograph stations in the existing array should be increased from seven to about twenty, and that they should be set out around the circumference of the volcano. It was also agreed that magnetometers, tiltmeters and inclinometers should be installed.

The committee also advised that to utilise the installations best, a volcanologist and a petrologist should, as an experiment, be employed permanently in the area. They would look after the equipment, make daily observations and do regular analyses of the material thrown up by the volcano. This would avoid, the committee hoped, the danger of over-reacting when there were insufficient data. □

USSR

Bottling up dissent

Vera Rich reports on recent developments concerning dissidents in the USSR and Eastern Europe.

LEONID PLYUSHCH, a former prisoner of conscience who was interned in the Dnepropetrovsk psychiatric penal institution, visited London recently. His presence formed a rallying point for all those concerned in the cause of human rights and freedom of thought in the USSR and the Comecon bloc.

Plyushch, a cybernetician who was arrested in 1972 for "anti-Soviet agitation and propaganda", was tried in his absence and interned as suffering from "creeping schizophrenia". His release was effected in 1975 following a massive campaign both from the mathematical and psychiatric communities abroad. Speaking in his native Ukrainian, a medium of expression which he explained was itself a symptom of "dissidence" to Soviet forensic psychiatrists, Plyushch declared that he did not wish to recall the details of his incarceration—the massive doses of neuroleptic drugs, the ambience of the genuinely sick and the "doctors" whose

white coats only partially covered their police uniforms.

In an interview with *Nature* he indicated he was concerned rather to campaign for those still in captivity, either his fellow internees in mental institutions or those who, like Vladimir Bukovskii or Semeon Gluzman, are now serving prison sentences for bringing the Soviet abuse of psychiatry to the attention of the world scientific community. Some 1,000 detainees, he estimated, are incarcerated in penal or ordinary mental institutions simply because their views on politics and human rights do not coincide with the official norms. Asked whether he had any regrets in his own case, Plyushch replied that, speaking with hindsight, he could now see that it would have been advisable to proceed more "canily", to be less open and naive, and to make sure that the authorities had less opportunity to gather a dossier against him.

Having acted as a liaison officer between the movement for self-determination in his native Ukraine and the Sakharov human rights committee in Moscow, Plyushch gave some interest-

ing new sidelights on the dissident movement. He stated that the campaign for human rights and civil liberties was primarily a movement of the scientific community, and had as yet little grass-roots following, thus differing sharply from the movement for religious liberty and the "national" movements in the Union (that is, non-Russian) Republics, which included all sections of the community. Only in certain specific areas, notably in West Ukraine (incorporated into the Soviet Union in 1939) is there a close link between the demand of the workers and peasants for better living standards and the campaign of the intellectuals for greater democratisation "on the Czech model".

As a cyberneticist himself, Plyushch stressed that the scientists in the dissident movement must put forward a "new kind of planning" if their ideas are to command the kind of mass support that he sees as the only sure foundation of democratisation.

The kind of union of workers and intellectuals which Plyushch advocates is an important feature of the new protest movement in Poland. Following the protests of workers in the Radom and Ursus plants against rising food prices, a defence committee was

A letter from the USSR

Nature has received this letter, addressed "to all scientists of the world":

Dear colleagues,

By this letter we want to call your attention to the tragic fate of biologist Sergei Kovalev. We want scientists to have a clear realisation of the conditions under which those who venture to protest against arbitrary rule are compelled to live in the Soviet Union. By the nature of their profession scientists strive for adequate cognition of the world. That is why we hope that it will be scientists who gain the best insight into certain features of the Soviet regime. This understanding could be of great importance.

Sergei Kovalev is a gifted scientist, specialist in the field of heart and cell physiology. In December 1974 he was arrested, and in December 1975, after a year of imprisonment, sentenced to seven years of prison camps of severe regime to be followed by three years in exile.

Kovalev's alleged "crime" was that in accordance with his convictions he could not and did not obey an unwritten Soviet law: to keep silent about all acts of arbitrariness and injustice done by Soviet authorities. Kovalev

was one of the first to join the Human Rights Movement. In May 1969 he entered "the Initiative Group" for protection of human rights. At a moment when "The Chronicle of Current Events" (a typewritten journal of political repression in the USSR) was savagely persecuted, Kovalev together with T. Velikanova and T. Khodorovich courageously announced that they would do their best to disseminate this journal since it gives true information about the violations of human rights in the USSR. All his activity in protection of human rights was imbued with noble spirit and humanism.

Sergei Kovalev committed no crime. In any open society he would be one of its most respected members. The Soviet authorities declared Kovalev a dangerous criminal. His imprisonment is not a mere limitation of freedom. In the camps they are trying to "rectify" Kovalev's convictions by isolation, hunger and humiliation. A renowned scientist is forced to do exhausting monotonous physical work, he is limited in correspondence (two letters a month), in visits of close relatives (one visit every four months at most, in practice still less). Malnutri-

tion also is one of the "rectifying" measures; accordingly, during three and a half initial years Kovalev will not be allowed to receive parcels.

But all this does not seem enough. Kovalev is constantly persecuted by the camp administration. He is not given qualified medical treatment and has no possibility of curing a painful chronic disease which makes his prison life unbearable, hard enough as it already is.

We call scientists of the whole world to make use of every opportunity to draw public attention to the tragic fate of Sergei Kovalev.

We call scientists to appeal to Soviet legislative, governmental and party bodies on behalf of Sergei Kovalev.

We call biologists to withhold scientific contacts with the Soviet Union until Sergei Kovalev is released.

ANDREI SAKHAROV, VALENTIN TURCHIN, YURI ORLOV, YURI MNYUKH, NINEL PANFILOVA, YURI GOL'FAND, VENYAMIN LEVICH, GALINA SALOVA, YURI GASTEY, ALEKSANDR LAVUT, TATYANA VELIKANOVA, ALEKSANDR LERNER, TATYANA KHODOROVICH, IGOR MEL'CHUK, ALEKSANDR KORCHAK, VLADIMIR ALBREKHT, NAUM MEIMAN, EFREM YANKELEVICH, ELENA BONNER, YURI SHIKHANOVICH, MARK AZBEL'.

set up, including writers, lawyers, historians and scientists. Among those already subjected to reprisals, biochemist Piotr Naumski has already suffered a short term of arrest, while Mirosław Chojewski, a chemist, has been dismissed from his post at the Institute of Nuclear Research in Swierk.

A letter from the Defence Committee to Academician Andrei Sakharov, appealing to his "moral authority and fellow-feeling", evoked a declaration from him that although he did not know what concerted actions could, at the present time, be aligned with the actions of the Polish defence committee, he was nevertheless seeking ways in which the Soviet human rights movement could "effectively cooperate" with similar movements throughout Eastern Europe.

There seems to be enough dissident activity to suggest that the time is ripe for such a concerted effort, if only one of moral support. In the Soviet Union a press campaign has been launched against Aleksandr Voronel, the founder of the illegal "Sunday seminar" for Jewish refusniks, denouncing him as a traitor. The seminar, which survived Voronel's departure for Israel in December 1974, is now approaching its fifth anniversary, and is planning a

special Jubilee session (Sakharov is to be on the jubilee Committee). Nevertheless pressure on the Seminar continues; recently several of its leading members, including physicist Mark Azbel, the organiser, were held by the police for several days.

In East Germany, the chemist Robert Havemann is subject to house arrest, for having protested against the exiling of Wolf Biermann, the dissident poet and ballad-singer. Havemann's dissident "career" dates back to 1964, when he was dismissed (on account of his "revisionist" views) from his post as Professor of Physical Chemistry at the Humboldt University, Berlin.

From Bulgaria it is understood that an attempt to disseminate some controversial material in *samizdat* form led to the removal of their author (a physicist) to a mental hospital. Although he was subsequently discharged, he was not reinstated in his university post but was instead retired on a disability pension, thereby effectively removing his ability to speak from a position of authority.

This appears to mark a new development. The dissemination of Soviet technology and ideas among the countries of the Socialist block is a basic concept of Comecon. So far, however, the incarceration of dissidents

in mental institutions has been primarily a Soviet phenomenon, although there have been hints of isolated cases in Czechoslovakia and the German Democratic Republic.

● Lord Todd had some words to say last week on the Royal Society's role regarding scientists and human rights. Delivering the Society's Anniversary Address, he said it was hard to see in what way the Society could occupy a special position. He pointed to the Society's adherence to the Declaration issued by the International Council of Scientific Unions and by its cooperation with that body in efforts to uphold it in all its member countries. In appropriate cases, he said,

the Society has drawn and will continue to draw the attention of the Soviet Academy of Sciences or the corresponding body in any other country concerned, as well as our own Government, to the facts and to the need for action with, I believe, good effect. It is my firm belief that the Society as such can achieve much more in this way than it can by subscribing to or issuing public declarations. For it must be recognised that a scientist, as such, is in the same position as any other citizen of his country, subject to the same laws and having the same obligations to the society in which he lives. His profession does not entitle him to special privileges which are denied to his fellow citizens; nor should it deny to him those privileges which are the right of every man. □

WEST GERMANY

Reactor reactions

A Correspondent reports on recent developments on the nuclear power front in the German Federal Republic.

THE future of nuclear power in West Germany depends critically on imminent decisions over the construction of nuclear reprocessing and storage facilities in Lower Saxony. The rumble of anti-nuclear feeling, which recently erupted in demonstrations at the Brokdorf power station site, led the Interior Minister, Werner Maihofer, to announce earlier this year that no new permits for the construction of atomic power stations would be issued until firm plans existed for dealing with spent fuel. The salt mines of Lower Saxony are considered the only suitable site for long-term waste storage. The Prime Minister of Lower Saxony was begged four weeks ago by Bonn Cabinet ministers to allow the plant to be built and seems to have been persuaded: the proposed site of the plant is to be announced soon. But determined local opposition will ensure that its path will not be smooth.

The 20% of Germans against nuclear energy probably entertain strongest fears about reprocessing and storage of nuclear fuels. But the most violent

protests have been not in Lower Saxony but at the site 50 km north-west of Hamburg where Kraftwerk Union is beginning to build West Germany's latest nuclear power station. Brokdorf, on the Elbe, has seen two ugly confrontations between demonstrators and police in the past few weeks, with many injured. The protests are not against any particularly unsavoury feature of Brokdorf but rather against nuclear expansion in general and the way industry is steadily transforming the lower Elbe region into another Ruhr.

The protests could equally well have been focused on Biblis, another Kraftwerk Union product and the world's biggest nuclear plant, which was forced to shut down for three months during the summer after screws had been found dislodged from a cooling pump. An even more controversial aspect of the plant is the intention of the owners, Rheinisch-Westfälische Elektrizitätswerke (RWE), to increase storage capacity for spent fuel pending construction of a reprocessing plant in Germany—RWE apparently find French and British reprocessing too expensive and prefer to sit on their fuel for an extra five or six years until the first German reprocessing plant is in action. Another worry for safety-con-

scious Germans is the prospect of the reactor which the chemical company BASF is to build in an urban area at Ludwigshafen. And a third reactor—that planned for Wyl on the Rhine—is as yet unstarted because of public protest. Even discounting the political element in the demonstrations, it is clear that the new anti-nuclear feeling is not to be taken lightly.

This is recognised by the Free Democratic Party, the junior party in West Germany's coalition government, who have voted at their party conference to put strict limits on new nuclear construction. Though the vote has no binding effect for the government it is thoroughly awkward for them and in particular for the Economics Minister, FDP member Hans Friedrichs, a strong nuclear supporter.

Altogether embarrassing timing for Siemens's announcement of its intention to take on AEG-Telefunken's 50% of Kraftwerk Union, the leading West German power station constructor, thus becoming sole owner. But Siemens is probably the happier of the two concerns. It is confident about the future of nuclear energy and has the resources to see the voracious and currently unprofitable Kraftwerk Union through the next few lean years. AEG-Telefunken, though glad to be rid of what it sees as an albatross, is not getting a particularly good deal. □

IN BRIEF

CERN subscription

At the time of going to press, it seems that the crisis over British international subscriptions, particularly to CERN, has been resolved. The problem arose because the government has been operating a strict cash limits policy, whilst subscriptions to international bodies have grown with the decline in the pound. In the Winter Supplementary Estimates, however, it has been possible to raise the Science cash limits by £2.5 million whilst dropping the University limits by the same amount. This step will not affect any university grants already announced — it

comes from an operational reserve now regarded as more than adequate. The remaining £3.5 million needed to fulfil the subscriptions comes from a variety of sources, the main being a CERN refund of £0.6 million on previous programmes and a re-examination of allowable accounting procedures for research councils in dealing with commissioned research.

Swedes propose nuclear law

New Swedish power stations will not be able to begin operating until they can

demonstrate that reprocessing and disposal of spent fuel can be carried out "in a completely safe manner" if a proposal made by the government last week becomes law in March as expected.

All companies building nuclear power stations would have to specify in detail in what form the spent fuel would be deposited and how the radioactive waste would be transported. The legislation would not affect the six Swedish reactors already in action or being loaded in preparation for action, but would apply to the four at present under construction.

SOME things are done very differently in the United States and in Britain. We are told that Mr Jimmy Carter, the President-elect, will have to appoint some 3,000 people in various offices. Many of those chosen may be rewarded for political services, others may be apolitical and some may even, in the past, have been his opponents. Though Mr Carter will not himself be able to choose each individual personally, he clearly bears a direct responsibility for the whole operation.

In Britain, particularly in the scientific field, changes of government have no immediate effect on the majority of appointments, and there is no wholesale turnover of office holders following a general election. Different governments have made many changes in the pattern of scientific management, generally with unfortunate results, but these have usually been implemented by a process of "general post" with the same faces reappearing with different titles and slightly different responsibilities.

Britain differs most from America in that the way in which many appointments are filled is shrouded in mystery. The full-time senior scientific posts, within government ministries, are mostly filled by the normal civil service machinery, though in many cases the methods by which the office holders are selected are as closely guarded as the register and membership of Cabinet committees. However, the results of this method are generally satisfactory, and sometimes brilliantly successful.

What is even less well understood, however, is the way in which the chairmen and members of influential bodies like our research councils or of the Nature Conservancy Council (whose ancestor was an independent research council until 1965) are selected. Although there are some very square pegs which have been thrust into round holes, in most cases the choice of members has been un-

exceptionable. Some have been active in science and have done distinguished research; a few are still active in their own fields. What is more doubtful is whether they are always the right men (I use the word deliberately, for few are women) to

By appointment**KENNETH MELLANBY**

carry out the duties now apparently expected of them.

It is generally believed that the idea of the independent research council, financed by government, was a good one, and did much to foster high-grade research in Britain. Originally the councils included laymen, some even being politically active members of both Houses of Parliament. The councils' functions were exercised by comparatively infrequent meetings to determine, or more often to approve, major questions of policy, and they interfered little with the general organisation of research and never with the actual work of the scientists they employed. From time to time there were criticisms, such as that even their most senior scientists were excluded from

membership of their own research councils.

I once heard this justified by a member, who said that it would clearly be improper for an employee to be a member of his own governing body. The speaker was a professor much engaged in university affairs; he was temporarily disconcerted when I suggested that his membership of his university's Council and Senate was, by analogy, equally improper. However, most of the active scientists probably preferred the freedom of their laboratories, and seldom hankered after public office.

Today members of these councils seem to be expected to take a much more active part in their work. Many of them are now paid a modest salary which, being honourable men, they feel they must earn. So meetings of the councils themselves, of their committees, working parties and preparatory groups take place interminably. The employed staff, including scientists who should be doing full-time research, spend more and more time "servicing" these meetings (though they are generally excluded from the more important sessions). My general impression is that all this extra work is almost entirely counter-productive, resulting in less and worse rather than more and better research. This is surely what might have been expected. Where research is concerned, no committee has ever had an original idea. The more such committees meet, the more they are likely to obstruct research.

Research councils are now complaining about their shortage of funds. If they ceased to pay their own members and if they met less often this would set free a modest sum to pay a few more bench workers. But more important, the reduction in the time wasted on and by the committees would do much to ensure that a greater proportion of the funds could be spent more fruitfully.

correspondence

Lavoisier's originality

SIR,—Antoine Laurent Lavoisier is generally credited with the independent discovery of oxygen and its role in combustion and respiration. But the existence of his personal copy of the complete works of John Mayow¹ suggests that his ideas were not as original as he claimed. Lavoisier's early detractors seem to have been justified even when they accused him of a lack of originality.

Mayow recognised the existence of oxygen, which he called *Spiritus nitro aereo*, in 1674 when he was experimenting in physiology at Oxford. He described the decrease in the "portion of air that made respiration possible and was essential to life as well as to the combustion of candles". He also described quite accurately the changes occurring in red blood cell pigment exposed to either "fresh" or "corrupted" air. He considered that the portion of air that made it "respirable" was fixed to this coloured compound in the blood cells and acted as an indicator of whether the blood was "respirable" (red, arterial blood) or "corrupted" (dark purplish, venous blood).

There are striking similarities between the writings of Lavoisier² and Mayow on this subject, although the former insisted that he did not know the work of the latter³. Some eminent eighteenth and nineteenth century scholars, however, including Cuvier⁴, maintained that he did, and Hoefer⁵ considered that Mayow was the "real father of modern chemistry and the inventor of the theory of respiration".

Lavoisier seems indeed to have known about Mayow's work because a letter³ to him from Mr Koenig of Strasbourg, dated 1767, contained an invoice for 118 books, among them a copy of Mayow's *De Sal Nitro*. As Mayow's tract *De Sal Nitro* was only published in the *Opera Omnia Medico-Physica* one must conclude that this book was the *Opera Omnia*. The book I found recently in the library of the Académie des Sciences de Paris, with the inscription 'De la Bibliothèque de M Lavoisier, Registre de Poudres et de Salpêtres de France, Inspector Générales du Roy', was one of the 1681 edition of *Opera Omnia*, published in The Hague. This book was in Lavoisier's personal library and then passed on to J. B. Dumas, who died in 1884. Dumas greatly admired Lavoisier and arranged for the publication of his works⁶. In

1937 the book was given to the Académie des Sciences.

Lavoisier, therefore, must have been familiar with Mayow's work when in 1777 he presented his memoirs on oxygen and respiration² to the Académie des Sciences, although in 1776 a letter from M Magalhaes⁷ to Lavoisier suggests that Lavoisier was only then looking for Mayow's works. His subsequent protestation of ignorance³ seems to have represented an eighteenth century version of scientific cheating.

Amazon rain forests

SIR,—The Amazonian rain forests are indeed "one of the world's great photosynthetic factories", as Thomas Jukes has recently stated (November 11, page 108), but he is wrong to add that they "maintain atmospheric oxygen". The total area of the Amazon basin rain forests is about 3×10^6 km² and the above-ground biomass is on average about 25,000 tonnes km⁻², but this huge mass of vegetation is not a net source of oxygen. Overall it is in equilibrium just as is any substantial area of climax vegetation.

Patches in the building and mature phases of the forest growth cycle do show net increase of fixed carbon and an accompanying release of oxygen, but this is balanced by decomposition of dying vegetation, in which oxygen is taken up, in patches of overmature forest and the following gap phase of the growth cycle. Man-made or natural catastrophes in which large areas are cleared and the vegetation destroyed by burning or natural processes of decomposition do locally and temporarily lead to fixation of oxygen, but these are followed by a vigorous regrowth of vegetation with a rapid build-up of biomass during which oxygen is released.

So the luxuriant regrowth which soon refills a jungle clearing is actually for a time a source of oxygen. What are altered by large scale clearance are the structure and species-composition of the forest, and unnaturally extensive clearance by modern man could progressively deplete the forest of its diversity and lead to reduction in numbers or even extinction of some plants or animals. There is also the possibility of altering reflectivity of the surface, hence the heat balance, hence, conceivably, local climate (Stewart P., *Commonw. For. Rev.*, 55, 155–157; 1976). These are the dangers to be countered as "development" of the rain forest takes place.

Seveso: putting it right

SIR,—With Alastair Hay's article on Seveso (October 14, page 538) is an item on alternatives to 2,4,5-T in which it is stated that Amcide is made by Nissan in Japan.

Just to put the record straight, Nissan Chemicals manufactures ammonium sulphamate but Amcide is the trade mark of Albright and Wilson Ltd, which markets ammonium sulphamate in the UK.

R. E. C. HAWKINS

Organics Sector,
Albright and Wilson,
Warley, UK

Alastair Hay adds: The article on alternatives to 2,4,5-T also mentions criticisms by environmentalists of the widespread use of polychlorinated biphenyls. In it the phrase "polychlorinated biphenyls (PCBs) such as DDT" should have read "polychlorinated biphenyls (PCBs) as well as DDT". Dichlorodiphenyltrichloroethane (DDT) is not, of course, a polychlorinated biphenyl.

The November 25 issue reported Dr Donald Lee as saying that 130 kg of dioxin (TCDD) was released in the accident at Seveso. Dr Lee has since indicated that his suggestion was that "given the worst possible situations up to 130 kg TCDD could have been produced". His figure does not refer to the quantity of TCDD discharged directly into the atmosphere; as far as he is aware no figures for the amount of TCDD remaining in and around the reaction vessel have been divulged.

news and views

Parity violation in atoms?

from F. E. Close

Is parity violated in atomic physics? According to the experiments being performed independently at Oxford and the University of Washington the answer may well be no (this issue of *Nature*, page 528). This is a very interesting result in light of last month's report (Benvenuti *et al.*, *Phys. Rev. Lett.*, **37**, 1039; 1976) claiming that parity is violated in high energy "neutral current" interactions between neutrinos and matter.

The majority of theoretical high energy physicists currently believe that the weak and electromagnetic interactions are probably unified with the consequence that the atomic physics and high energy neutrino experiments should have shown similar behaviours with respect to parity. Consequently the atomic physicists' observations are highly significant and potentially dramatic for our understanding of Nature. To appreciate their relevance it is worthwhile surveying the developments of the past few years that have set the background for these experiments.

Unification of the weak and electromagnetic interactions

The unification of Nature's forces has long been the aim of physicists. In the 19th century Maxwell unified electricity and magnetism and in the past few years there has been an increasing belief among physicists that the familiar electromagnetic interaction may well be unified with the weak interaction. This latter mysterious force is responsible for β decay and is intimately linked with parity violation. If this unification idea is correct, then it would rank as one of the major advances in our understanding and hence much effort has been directed towards investigating it.

On the theoretical front there is the unified model of Weinberg (*Phys. Rev. Lett.*, **19**, 1264; 1967) and Salam (in *Elementary Particle Physics*, edit. by Svartholm N., 367, Stockholm, 1968). This idea was attractive but appeared to suffer from the difficulty that at high energies certain processes had infinite

probability. In the past few years there has been an upsurge of interest in this model as a result of three discoveries each of the first order of magnitude in significance.

In 1971 G. 't Hooft of the University of Utrecht showed that the theory was renormalisable, that is the infinities are no different from those that we are used to meeting in quantum electrodynamics and can be removed by traditional tools. This meant that for the first time one had a viable theory of weak interactions which did not violate any known general principle such as relativity, causality and unitarity and which, furthermore, suggested an intimate relation between weak and electromagnetic interactions.

On the experimental side was the discovery of "neutral current" interactions in which a neutrino interacts with matter without transfer of electrical charge, in contrast to the previously well known "charged current" interaction where the neutrino turns into a charged lepton (e^- or μ^-) with associated transfer of electrical charge to the target. That such neutral currents should exist was predicted in the Weinberg-Salam model and so their discovery was greeted with excitement (*Nature*, **245**, 119; 1973; **249**, 211 and **250**, 186; 1974). The charged current interactions have been known for many years to violate parity. The model predicted that the neutral currents should also be parity violating and this was confirmed by neutrino experiments only last month (Benvenuti, *op cit.*).

The discovery of neutral currents raised a problem, namely why is strangeness conserved in their interactions, in contrast to the charged current case? The theoretical answer was to postulate that a new family of particles should exist with a property called charm and with rather distinctive production and decay behaviours which have the effect of cancelling the unwanted strangeness-changing neutral currents (see *Nature*, **259**, 622; 1976). Two years ago this month came the

momentous discovery of the J/ψ particle (see *Nature*, **252**, 438, and **254**, 387; 1975) which led to the Nobel Prize for physics, being awarded jointly to B. Richter and S. Ting just a few weeks ago. This discovery was like finding a previously hidden window and the view through it led to the discovery this summer of the charmed particles. Consequently all the phenomena required for the unified theory to be valid were indeed being seen. Furthermore, by July of this year, a wide variety of data was being reported at the International Conference in Tbilisi USSR (see *Nature*, **262**, 537; 1976) in accord with the original unification idea of Salam and Weinberg.

Put all of these discoveries together and the excitement about unified theories of weak and electromagnetic interactions is natural.

Parity violation in atoms

According to the Weinberg-Salam model one should see parity-violating effects not only in $\nu \rightarrow \nu$ but also in processes involving electrons ($e^- \rightarrow e^-$) or muons. In these latter cases the parity-violating weak neutral current is swamped by the parity-conserving electromagnetic current; hence one would have to look for subtle effects. One such effect would be that a parity forbidden electric dipole transition could take place between atomic energy levels such as $1S_1$ and $2S_1$ in addition to the parity allowed magnetic dipole transition. It is effects associated with such small "wrong parity" admixtures (see Brodsky, S. and Karl, G., *Parity violation in atoms*, in *Comments on Atomic and Molecular Physics*, **5**, 63-69; 1976) that are being looked for by Sandar *et al.*

As these experiments currently stand, the predictions of the Weinberg-Salam model supplemented by atomic physics calculations appear inconsistent with the data.

As stated by both groups, their results are consistent with no parity violation. At present the discrepancy can conceivably be the combined effect

of systematic errors in atomic physics calculations and systematic uncertainties in the experiments. If, however, this state of affairs persists to a factor of ten below the present level and future high energy neutrino experiments (such as those about to begin at the CERN SPS in Geneva) continue to uphold the parity violation recently reported, then a rather paradoxical situation will have arisen in the light of currently favoured ideas.

The conclusion would probably be that neutrino interactions violate parity both when charge is transferred or when the neutral current process occurs. The parity-violating neutral

current with neutrino beams would have no obvious relation with electron beams which conserve parity. This is quite a tenable viewpoint—if one doesn't believe in unified theories! Alternatively, one might argue that there is some strange energy dependence whereby the high energy experiments show parity violation which is less marked at low energies (as in atomic physics). Whether such a possibility could be incorporated into the unification ideas is not clear. It also isn't clear, yet, if we have to worry. However, the clear blue sky of summer now has a cloud in it. We wait to see if it heralds a storm. □

about 30 tons is similarly driven through a 5.6 m rack and worm.

The azimuth and elevation positions are read into the computer from digital systems on the telescope axes and conventional drive systems give following accuracies on sidereal coordinates fed into the computer to ± 0.3 arc s. In actual operation the final guidance is by manual or automatic photoelectric corrections, on the object or offset star. These outputs are both fed into the computer and also operate quartz plates which adjust the position of the image. Experience has shown that the operational accuracy is one-fifth of the diameter of the image. That is, if the seeing disk is 1 arc s the guidance is accurate to 0.2 arc s. At the prime focus the manual setting system only is available but both manual and photoelectric devices are available at the Nasmyth foci. The controversial question of the problem of correction for image rotation in an alt-azimuth telescope appears to have been solved satisfactorily by these arrangements. In a 20 min exposure the errors in the correction for field rotation do not exceed 0.3 arc s. The slewing speed of the telescope is 45 deg min^{-1} in azimuth and 30 deg min^{-1} in elevation.

The finder telescope is of 70 cm aperture and objects of 17 mag are visible on the television display. Two fields of view, 30 arc min or 11 arc min, are available. At the prime focus guidance can be made directly or by offset on a 19 mag object. A television system for use at the prime focus is under development and it is expected that this will enable direct guidance to be carried out on objects to a limiting magnitude of +21.5 in blue colour.

The mirror

The 6 m mirror is of Pyrex glass. During the casting of the blank two small bubbles appeared and these spread somewhat during the grinding process. Small baffles in the region of the prime focus blank out these regions, but the consequent loss in intensity is only 10%. Otherwise the mirror has fulfilled expectations and although it will be replaced eventually by a mirror of SITALL material (the Soviet equivalent of CERVIT) there is understandably no great anxiety about the probable delay. The position on the availability of Soviet mirror blanks in SITALL is that blanks of 2 m are now available and the 6 m blank is expected to be available between 1979 and 1980 and the probable date for installation in the telescope is thought to be about 1983. The focal length of the 6 m mirror is 24 m giving a field of view at the prime focus of 2 arc min which can be increased to 20 arc min by the field correcting plates. The operating posi-

The Soviet 6 m telescope

from Bernard Lovell

It has been difficult in the West to obtain consistent information about the state of the Soviet 6 m optical telescope. It was therefore with particular interest that I received an invitation from the Soviet Academy of Sciences to visit the recently created Astrophysical Observatory, in the North Caucasus. The principal instruments of this observatory, which has the status of an Institute of the Academy, are the 600 m RATAN radio telescope and the 6 m optical telescope. A recent account of the RATAN radio telescope has been published (*Nature*, **262**, 535, 1976) and the following account deals mainly with the 6 m telescope as it existed in mid-October 1976 when I visited the observatory and talked with Dr I. M. Kopylov the director, Dr B. K. Ioannisiiani the chief designer and several members of the observatory staff.

Before choosing the site, I was told, fifteen areas in the Soviet Union were tested. It seems that an area in the Asian Republics might have been chosen but for the difficulty of transportation and constructing the telescope in such a region, and eventually the North Caucasus region was favoured. The telescope is 250 km from the airport of Mineralniye Vody, a 1 h 45 min jet flight from Moscow. The route rises slowly until the small town of Zelenchukskaya is reached 210 km from the airport and on the outskirts of this town the RATAN radio telescope has been constructed at an altitude of 1,000 m. From Zelenchukskaya the road continues normally for a further 24 km to where the new scientific village of Nizniy Azkhyz is

under construction. This village at present consists of a block of 70 flats for the scientists, a kindergarten, two shops and a cinema. The main scientific laboratory is under construction and more schools, a hotel and restaurant for visiting scientists are planned. From here an entirely new road 17 km long has been constructed to the telescope site which is at an altitude of 2,100 m in Stavropol territory, latitude $44^{\circ}44'N$, longitude $02^{\circ}40'E$. A small hostel in which we were housed provides a pleasant residence in beautiful surroundings about 800 m from the telescope. When the hotel in the village is complete this hostel will be used only by those using the telescope.

Design and guidance

The design of the telescope is unique in that it is the first large optical telescope to make the break from the conventional polar axis to an alt-azimuth mount. This has resulted in a most elegant construction and the system is clearly a great success. The rotating part of the telescope weighs 800 tons carried on six oil pad bearings and a locating but not load-bearing pedestal beneath. The vertical is maintained to 2 arc s by this system. The azimuth drive is through a 5.6 m gear and worm; the 5.6 m rack with 512 teeth was cut in one piece. This precision worm drive is protected from accidental overload by a spur gear and pinion, mounted immediately beneath it. If the load on the main drive rack reaches a specified level the worm is automatically shifted laterally so that the overload is taken on the subsidiary system. The elevation cage weighing

tions are either at the prime focus or at the two Nasmyth foci. The image scale is $0.12 \text{ mm arc s}^{-1}$ at the prime focus and $0.90 \text{ mm arc s}^{-1}$ at the Nasmyth foci.

Recording systems

In addition to direct photography two spectrographic cameras are available at the prime focus. Three gratings of 200, 300 and $600 \text{ lines mm}^{-1}$ and a selection of optical systems give dispersions in the range 60 to 370 Å mm^{-1} . One Nasmyth focus is occupied by equipment for stellar spectroscopy. The other focus houses an echelle spectrograph with two gratings. One with $100 \text{ lines mm}^{-1}$ giving a dispersion of 36 Å mm^{-1} in the range $3,200$ to $6,700 \text{ Å}$, and the second with 50 lines mm^{-1} giving a dispersion of 45 Å mm^{-1} in the range $6,500$ to $11,000 \text{ Å}$. The modern Kodak emulsions are used and up-to-date emulsion treatment facilities are available.

As regards electronic recording systems a one to three stage image tube system is working in the laboratory and will be tested at the prime focus before the end of November. Initially the spectrum will be recorded photographically but I was shown a digital recording system in an advanced state of development in the laboratory and was informed that this would be in use on the telescope in 1977. In this system real time sky subtraction will be available.

Sky conditions and sensitivity

The site has been carefully chosen to provide excellent seeing conditions. From the limited time for which the telescope has been in use the opinion is that 100 nights per year are absolutely clear and 200 nights about half clear, and for about 20% of the time the seeing conditions are 1 arc s. It is believed that temperature effects on the Pyrex mirror contribute significantly to this disk and that this 20% figure may be reduced to 0.5 arc s when the SITALL mirror is available. The present sensitivity of the system is that objects of +24 mag in blue colour with a signal-to-noise ratio of 3 to 5 are obtained with exposures of 30 to 40 min. Objects of magnitude +25 in blue appear with these exposures with a 64% probability of identification. In red the limit is +23 to +23.5 magnitude for a 90-min exposure. Dr Yu. Karovjakovsuy kindly presented me with a recent photograph of NGC 2419 obtained in blue colour with a 40 min exposure in which stars of +24 magnitude are clearly visible.

Contrary to the system favoured at Kitt Peak and Siding Spring the dome is effectively at ground level. Naturally the rotation is controlled by the telescope drive computer and the con-

struction, offices, laboratories and general facilities are of the highest quality. The telescope is already being visited by a considerable number of groups of the public. They are shown a film of the construction of the telescope in a lecture theatre inside the dome and can inspect the telescope through a viewing gallery. The telescope area itself is air conditioned and temperature controlled. The temperature is set to the predicted night temperature some hours before observations commence.

The chief designer of the telescope, Dr Ioannisiani, told me that the cost of the telescope itself together with associated equipment was about 30 million roubles. At current exchange rates this is of the order \$36 million, although it must be remembered that because of large variations in the cost of labour and materials the equivalence must be treated with caution. The cost of the dome, of the road up the mountain, the buildings at the observatory site and the erection of the new village, in addition to the cost

of the RATAN radio telescope implies that the Soviet Academy has invested a substantial sum of money in this new Institute. This courageous enterprise has given Soviet astronomers an unsurpassed instrument for the study of the heavens. The final tests and adjustments of the telescope by the observatory staff will be completed shortly and from January 1977 it is expected that the telescope will be in regular use for astronomical research. The instrument probably marks an historical epoch in the development of astronomy for two reasons, first because it is unlikely that a larger telescope will ever be constructed on Earth, and second because the success of the alt-azimuth mounting may lead to the abandonment of the polar axis design for any future large telescopes.

I wish to express my gratitude to the Academy of Sciences of the USSR for the invitation to visit this telescope and to Dr Ioannisiani, Dr Kopylov and many members of the observatory staff for their kind attention during my visit. □

Rethinking human evolution

from our Palaeoanthropology Correspondent

MANY areas of science occasionally make rapid advances when new data, new analytical tools and new areas of investigation suddenly open up new realms of perception, insight and knowledge. During such a phase the accumulation of data may proceed so rapidly that the older theoretical foundations to which these data are applied may require rethinking and revision. When that occurs it is necessary to step aside briefly in order to reassess those theoretical frameworks from the vantage of the new evidence. The study of fossil man has recently been undergoing such a period of saltatory expansion. The abundant new African material, from Lake Turkana (formerly Lake Rudolf), Laetolil and Hadar has accumulated so rapidly that there has been little time to reflect on how this material may affect current theories of evolution and our understanding of certain taxonomic categories.

Within the early years of this decade students of human evolution have already had to recognise two important and inter-related alterations in earlier theories of human emergence. The first of these concerned the evidence that two types of hominid had existed contemporaneously within Plio-Pleistocene times. Although some work had earlier

indicated such sympatry, the Lake Turkana and Hadar discoveries have provided virtually unquestionable evidence that at least two forms of hominid had coexisted (see Leakey and Walker, *Nature*, **261**, 572; 1976).

Such evidence indicates that the earlier and simpler models of "straight-line" evolution (for example, *Ramapithecus* → *Australopithecus* → *Homo*) could not be substantiated in the fossil record. Thus, the evolution of the Hominidae is more complex, and ultimately more interesting, than previous indications.

The second implication of the new fossil material is that the genus *Homo* may be far older than previously thought. A recent paper in *Nature* (M. Leakey, *et al*, **262**, 460; 1976) suggests the presence of *Homo* at Laetolil, Tanzania as early as 3.77 Myr ago. In that suggestion the authors have demonstrated, perhaps unwittingly, one of the more serious problems in studies of early man today. That problem is a lack of usable and valid definitions for genera within the family Hominidae. In that paper, the authors point out certain similarities between the jaws and teeth of the Laetolil hominids and others from such sites as Olduvai, Sterkfontein and Taung. Yet the Sterkfontein hominids have often been

placed within the gracile australopithecine group and Tobias has favoured placing the Taung child within the robust australopithecines. The acknowledgement of such morphological affinities does not strengthen the final attribution of the Laetolil hominids to the genus *Homo*.

However, the suggestion that this, or any material, belongs to the genus *Homo* should not rest solely on the presence of certain dental features. All hominids share a basic, underlying morphological pattern which is particularly evident in the jaws and teeth. The ultimate placement of fossils in the genus *Homo* must be based, first, on a clear statement of what characters constitute that genus and how it is distinguished from other contemporaneous hominid taxa.

Walker has recently (*Earliest Man and Environments in the Lake Rudolf Basin*, edit. by Coppens, *et al.*, Chicago University Press, 1976) taken a step in this direction by proposing a working model for a differential diagnosis between the Plio-Pleistocene hominid genera. Admittedly tentative, this model is of interest in that it focuses on a broad spectrum of cranial and facial features but avoids use of specific dental characters. Such a model could provide a useful point of departure for a broader and widely acceptable definition of early hominid genera. Ultimately, however, such a definition must also be based on character complexes of the post-cranium. For example, we are now in a position to begin discussing limb proportions, weight distributions in the lower limb and the structure of the hip and knee joints in the early hominids.

Walker's model also provides a warning concerning the problems inherent in basing attributions on single characters or on a tightly inter-dependent suite of characters. When the cranium of KNM ER 1470 was found in 1972 it was widely considered to have belonged to an early member of the genus *Homo*. This attribution was based almost entirely on its relatively large cranial capacity (about 775 cc) and on skull characters related to that size. Walker argues, however, that when the absolute size factor is de-emphasised the total morphology of this skull does not demonstrate clear affinities with *Homo*. Although Walker stops short of attributing the KNM ER 1470 cranium to *Australopithecus*, its position within *Homo* is clearly now uncertain. The taxonomic position of the Laetolil hominids must also be considered uncertain. Both, however, provide useful examples of some of the intrinsic problems in our current poorly defined taxonomic schemes. The large amount of newly available data should, hopefully, be put to good use in improving

our recognition of the distinctions between the early hominid groups. □

Mathematics and casinos

from Robert M. May

JAMES BOND fans will recall the climactic moment of the first book, *Casino Royale*, when the fate of Bond's mission hung on a single hand of chemin-de-fer. This two-person zero-sum game is one of several variants of the generic game baccarat, in which each player is dealt two face-down cards, and has the option to add one face-up card (the banker deciding last). The aim is to maximise the point count of the hand, modulo 10, with court cards counting as zero; thus 9 is the best count. The game is mathematically interesting in that non-trivial game theory concepts are appropriate. The complete minimax solution for chemin-de-fer with an infinite deck (or, equivalently, a finite deck sampled with replacement) was given by Kemeny and Snell (*Am. Math. Monthly*, **64**, 465; 1957), and shown by Karlin to be an example of a general result (*Mathematical Methods in Games, Programming and Economics*, Pergamon, London, 1959). The player's optimal strategy is deterministic in all cases but one: when his first two cards total 5, he should draw with probability 9/11 and stand with probability 2/11. The banker likewise acts deterministically unless his count is 6 and his opponent has not taken a third card, whereupon he draws with probability 859/2288 and stands with probability 1429/2288. When both players adhere to their minimax strategy, the banker has an average gain of 1.28% of the stake. In the heart-stopping hand, Le Chiffre held a count of 3, having just dealt Bond an exposed (third) 9 card, and both players agonised over his decision whether to draw a third card. As this was in 1953 or earlier, their ignorance may be pardoned. Kemeny and Snell's exact optimal strategy mandates that Le Chiffre draw (as he eventually did).

Before July 1, 1970, the British Gaming Act covering banker's games permitted any game so long as the "chances" in it were equally favourable to all players, including the banker. This fatuous legislation initiated some fascinating statistical studies (Downton, *J. R. Statist. Soc. A* **132**, 543; 1969; Downton and Holder, *loc. cit.*, **135**, 336; 1972; Holder and Downton, *loc. cit.*, **135**, 221; 1972; Downton and Lockwood, *loc. cit.*, **138**, 228; 1975 and **139**, in the press; 1976), as the "chances"

generated by games like baccarat and blackjack with finite decks are not readily amenable even to sophisticated mathematics in conjunction with fast computers. The new Gaming Act is more sensible. It allows four games (roulette, dice, baccarat, blackjack) to be played in licensed clubs, and defines the rules of play.

Downton and his colleagues have explored the mathematical properties of the four permitted games. Roulette and dice are games of pure chance, and are relatively simple to analyse, although some interesting features emerge (of which more below). For baccarat in its chemin-de-fer version, the banker's expected gain of 1.28% under optimal play with an infinite deck is independent of the player's strategy (Downton and Holder, *op. cit.*), so that this game is also effectively one of pure chance for the player. The use of a finite deck makes for vastly greater mathematical complexity (Downton and Lockwood, *op. cit.*). Depending on the size of the deck, measured in units of 52 card packs, and on the cards that have gone before, there are situations where the banker should randomise his decision when holding 3 and giving 8, holding 4 and giving 1, holding 5 and giving 4, holding 6 and giving 6, as well as the Kemeny and Snell case of holding 6 and giving no card (but Le Chiffre should still always draw when holding 3 and giving 9). The odds are but little affected by all the complications (the banker's expected gain with a three-pack deck is 1.31%), and Kemeny and Snell's strategy remains an excellent approximation with finite decks.

In blackjack the aim is to get close to a count of 21 (court cards counting as 10) without exceeding it. Subtle variations in the rules make for interesting differences in the player's strategies and in the odds (see the papers by Downton and Holder). The variant played in American casinos attracted much attention in the 1960s, when the perfect player was shown to enjoy an advantage of about 0.1% with a one-pack deck (Thorp, *Proc. natn. Acad. Sci. U.S.A.*, **47**, 110; 1961; *Rev. Int. Stat. Inst.*, **37**, 273; 1969; Epstein, *Theory of Gambling and Statistical Logic*; Academic Press, London, 1967). With a four-pack deck, the odds favour the bank. The version permitted in Britain under the current Gaming Act gives the bank a gain of 0.13% and 0.59% with one- and four-pack decks respectively. Casino pontoon, the variant played in most British midland clubs in the 1960s under the old Gaming Act, gives the banker an edge of 1.57% and 0.63% with one- and four-pack decks: notice here that, unlike blackjack, the bank's advantage de-

creases with increasing deck size. It is amusing that, misguided by the American experience, most midland clubs played with four-pack decks, thereby diminishing their advantage. Of course few players have the skill to achieve these odds, and the bank typically wins around 2–15% of the stake per hand. Downton has verified these figures in an extended series of undergraduate laboratory experiments.

This work has intrinsic interest. It can also be tortured into yielding two morals for ecologists. Downton notes that an interesting characteristic of any game of chance is the "gain ratio", defined as the bank's average gain per unit stake divided by the standard deviation: the gain ratio is the reciprocal of the coefficient of variation. Although all players are doomed to long-term losses, the smaller the gain ratio the higher the probability that a player will win (or, equivalently, will survive through) any one session. In roulette, gain ratios vary from 0.46% playing single members to 3.77% playing groups of 24; in dice or craps they range from 0.99 to 4.42%; in chemin-de-fer with best play the gain ratio is 1.34%. The significance of the gain ratio is illustrated by considering a casino which spins its roulette wheel 90 times per hour. Suppose 20 people each bet £1 on each spin over an 8-hour session. The bank's expected winnings are £390, but the standard deviation is £189 if all players bet on groups of 12 numbers, £706 if all bet on single numbers. This is a consequential difference. The processes whereby, in Reddingius's memorable phrase (*Oecologia*, 5, 240; 1970), plants and animals "gamble for existence" in an unpredictable world has many similarities with these games. The notion of "gain ratio" is likely to have fruitful applications in ecology.

Casinos and gamblers are usually ignorant of the mathematical structure of their games and strategies, which have, rather, evolved by an intense and highly motivated process of trial and error. In some respects they therefore invite analogies with biological processes of evolution by natural selection. This is particularly so for the way primitive societies may, or may not, have unconsciously "evolved" optimum strategies of resource management. The advantage of gambling games is that the empirically evolved strategies can be compared with the exact optimum ones. Chemin-de-fer provides a beautiful example: the optimum strategy is for the banker to vary his choice of drawing or standing only when he holds 6 and has given no card; most clubs have mandatory instructions to the dealer, and these used to be Crockford's drawing card which

allowed options in three cases, namely, holding 6 and giving no card, holding 5 and giving 4, and holding 3 and giving 9; since 1972 the instructions provided by the Casino Association of Great Britain allow the banker a choice in the latter two cases only. Although the differences are inconsequential, it is notable that the strategies chosen by the casinos were never the best, and have changed for the worse. Casino owners should read Downton's work. □

Surprises in the Magellanic Clouds

from M. G. Edmunds

THE research potential of the Magellanic Clouds—the two nearby galaxies easily visible to the naked eye in the Southern Hemisphere—is underlined by the surprising result of a recent investigation of a star cluster in the larger of the two Clouds. An Australian group (Gascoigne *et al.*, *Astrophys. J.*, 209, L25; 1976) have used the Anglo-Australian 3.9-m telescope to study NGC2209, one of the so-called "intermediate age" globular star clusters in the Clouds.

For stars it is notoriously difficult to assign a reliable age by appearance. But for a cluster of stars, the morphology of a plot of colours of the stars against intrinsic brightness can yield a fair guess. The method essentially works by looking for the highest mass (that is, brightest and bluest) dwarf stars which are only just beginning to evolve into giants. This "turn-off point" from the Main Sequence of dwarf stars can then be compared with computed models of stellar evolution to estimate an age.

In physical appearance a globular cluster has a characteristic spherical shape, held together by the mutual gravitational interaction of the stars. All globular clusters in our own Galaxy seem to have formed at the same time as, or not very much later than, the formation of the Galaxy itself—they are "old" objects. In the Magellanic Clouds there exist globular clusters which have almost certainly formed recently, as evidenced by the existence of bright young blue dwarfs which will live only a short time as dwarfs on the Main Sequence. The "intermediate age" clusters formed sometime between the young and old. Since there are only old clusters in our own Galaxy, these young and intermediate age Magellanic Cloud objects are of great interest. What is surprising is that the Aus-

tralian group find good evidence that the stars in the NGC2209 cluster have relatively few heavy elements ("metals") in them, only about one-sixteenth of the solar abundances, and yet they estimate the age of the cluster as a mere 8×10^8 yr compared with a probable age in excess of 10^{10} yr for the Large Cloud itself. The problem is that the interstellar medium in the main body of the Large Cloud, as determined by several independent investigations of the gaseous nebulae, is certainly not less than one-half solar. If the cluster were very much older, then its composition could be explained by saying it formed out of metal-poor gas, and that metal synthesis in the supernovae explosion of massive stars had enriched the interstellar medium since then. But here is a cluster which is apparently fairly recently formed, and should therefore reflect the present chemical composition of its precursor interstellar medium. It is true that the cluster is one of the most outlying—some 6° or 6 kpc away from the centre of the main body of the Large Cloud, but it is unlikely that the chemical composition of the interstellar medium varies so drastically across the Cloud. Perhaps an outlying cloud of gas somehow survived with very little star formation and consequent metal enrichment, until efficient star formation was suddenly induced.

The metal abundance of the cluster seems well demonstrated since the group used two independent methods. One method relies on the displacement of the locus of stars (relative to Galactic solar composition star clusters) on the colour/brightness plot, due to the weakness of absorption by metal lines in the blue spectral region. A second estimate comes from taking advantage of the light-gathering capacity of a large telescope and isolating just a few spectral lines in two of the stars by interference filters. A comparison of the line strength with that observed for stars in clusters of known composition yields a metal abundance estimate. Both methods agree that the cluster is considerably metal deficient.

The accurate aging of the cluster is more uncertain. The authors unfortunately do not quote error limits on their estimate. An inspection of their published data suggests that using their aging method, errors would not push the age back further than 2×10^9 yr—still young compared with old clusters and the probable age of the Clouds.

If the age of the cluster is confirmed in subsequent work, then considerable revision of our ideas about the chemical homogeneity of the interstellar medium in galaxies may be required. Investigation of other similar clusters in the Clouds will be awaited with interest. □

Salt tolerance in halophytes

from C. D. Field

In large areas of the world, the soil is too saline to support economic agriculture and more land becomes non-productive each year because of salt accumulation. So recent research into the ability of halophilic plants to survive in very saline environments has taken on a new importance.

The basis of the salt tolerance of halophilic plants is their ability to maintain and tolerate a high salt concentration in the cell. Since many halophytes show a positive growth response to salt in their environment (although they may also survive in a salt-free environment) it has been argued that as well as participating in the necessary osmotic adjustments, the high ion concentration may also be required by the plant for normal metabolic activity.

One possibility might be that the enzymes of halophilic plants, like those in salt-tolerant bacteria, require high salt concentrations for optimal activity. But this possibility seems to have been disproved by recent work (see Flowers, *Ion Transport in Plant Cells and*

Tissues, North Holland; 1975) which shows that *in vitro*, enzymes from halophytes are inhibited by ion concentrations much lower than those expected to occur in the cytoplasm, and very similar to those tolerated by enzymes from non-halophytes. Flowers has recently shown (*Proc. R. Soc. Lond.*, **B273**, 523; 1976) that malate dehydrogenase from the halophyte, *Suaeda maritima*, is activated at electrolyte concentrations similar to those required to activate the enzyme from non-halophytes. All the evidence therefore points to the conclusion that halophyte enzymes are neither particularly salt resistant nor salt requiring.

This leads to the idea that the excess sodium ions must be isolated from the cytoplasm in some way. Indirect evidence from efflux analysis and ion mobilities in tissues of halophytes suggests that sodium ions are retained in the vacuole (Flowers, *op. cit.*) and Jeschke and Stelter (*Planta*, **128**, 107; 1976) have shown that sodium ions are largely excluded from the cytoplasm of the halophyte *Atriplex* and barley, using flameless atomic absorption spectroscopy on thin slices of single roots.

This however raises enormous problems of osmotic imbalance between the

cytoplasm and the vacuole, which on this hypothesis would hold most of the salt accumulated in the cell. This osmotic imbalance could only be overcome if the water potential of the cytoplasm could be lowered, so that it will attract water from the vacuole and remain hydrated. This could theoretically be achieved in various ways. The cytoplasm might have an unusually high water-holding capacity arising from its structure, Donnan equilibria might exist between cytoplasm and vacuole, or a non-toxic osmoticum might accumulate in the cytoplasm. There is little evidence for the first two possibilities, but there is increasing support for the third.

Some years ago Stewart and Lee (*Planta*, **120**, 279; 1974) proposed the amino acid proline as the possible osmoticum. They found that in many halophytes proline accounts for more than 30% of the amino acid pool, whereas it is much less in glycophytes although the level in some species increases in response to salt or water stress. Stewart and Lee also showed that proline concentrations of up to 600 mol m^{-3} do not inhibit enzyme activity *in vitro*.

At a recent International Workshop on transmembrane ionic exchanges in plants (CNRS, Rouen, July 1976) Wyn Jones *et al.* put forward another candidate, the quaternary ammonium compound betaine, for the balancing osmoticum. They demonstrated that the betaine content of the halophytes *Atriplex spongiosa*, *Spartina x townsendii* and *Suaeda monoica* increased with external sodium chloride concentration, and that there was a close correlation between betaine accumulation and an increase in sap osmotic pressure above about 400 osmol m^{-3} . They also found that the *in vitro* activity of malate dehydrogenase was not inhibited by 1 M betaine, and that in the presence of low malate concentrations betaine provided partial protection to the enzyme against potassium chloride and sodium chloride toxicity.

These results suggest that betaine may have a similar role to proline in the cytoplasm of certain halophytes. Flowers has recently confirmed that similar levels of betaine occur in the halophyte *Suaeda maritima*. But in all cases direct experimental demonstration of betaine in the cytoplasm is still needed.

A simplified picture of a typical halophilic plant cell now emerges in which the potassium ion and sodium ion concentrations in the cytoplasm are of the order of 100 mol m^{-3} and 150 mol m^{-3} , whereas the vacuole has corresponding concentrations of 100 mol m^{-3} and 500 mol m^{-3} (Flowers *op. cit.*), and the osmotic balance in the cytoplasm is preserved by proline

Hormones, ducks and sex

from John Krebs

It is well known that steroid hormones influence sexual and aggressive behaviour in many vertebrates. These established and documented effects are of a rather long term nature, involving changes over developmental, seasonal and similar time periods. Recently, J. Balthazart (*J. Zool.*, **180**, 155; 1976) has suggested that much shorter term changes in behaviour might also be caused by fluctuations in hormone levels. He recorded the daily pattern of behavioural activities in two groups of five male domestic ducks housed in outdoor cages during winter. At the same time he took serial blood samples from each male to measure plasma testosterone.

The most interesting behaviour categories for the present discussion were courtship displays, mating attempts, and aggressive attacks on other males or females (there were two females in each group of males). Courtship and mating activity decreased through the day after an early morning peak, although some of the other activities did not show a similar daily rhythm, so there was not simply an increase in lethargy as the day progressed. In relating

these changes to plasma testosterone, Balthazart found that the hormone was at a higher level early in the morning than at other times of day, correlating well with the frequency of sexual behaviour. Further, some of the contrasts between the two groups were associated with hormonal differences. One group showed an increase in both display frequency and hormone levels in the afternoon while the other showed neither, but this second group had a higher level of sexual activity overall and a higher mean level of testosterone.

Behavioural differences between individual males did not relate clearly to hormone levels. There was a very slight tendency for males with higher testosterone levels to be more sexually active, but differences in daily rhythm did not relate to hormonal differences.

Balthazart's results raise an intriguing explanation for a mechanism of short term changes in behavioural activity, but it still has to be shown that the changes in hormone level cause the behavioural changes, rather than the other way round.

or betaine.

As with most models anomalies inevitably arise and in this case some of the marine algae raise pertinent questions. In *Valonia ventricosa* the cytoplasmic potassium level has been reported as of the order of 440 mol m^{-3} and the sodium level as about 40 mol m^{-3} whereas the corresponding vacuolar levels are about 620 mol m^{-3} and 40 mol m^{-3} (Gutknecht, *Biol. Bull.*, **130**, 331; 1966). The cytoplasmic potassium concentration in this instance is well above the demonstrated level for inhibition of enzymes from other halophytes. A re-examination of the ion concentrations in the various compartments of this particular alga is clearly indicated. At the same time it would be useful to find whether any metabolic adaptation such as adaptation of enzymes to salt has occurred or whether any compatible organic solutes are present in unexpectedly high quantities.

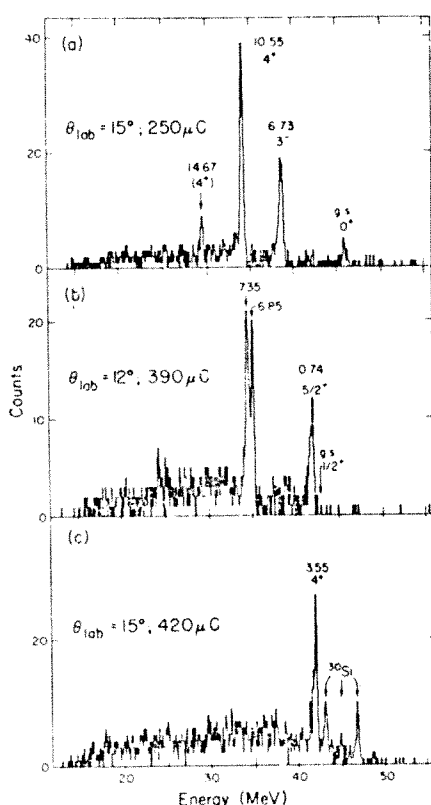

Nuclear spectroscopy with the (α , ^3He) reaction

from P. E. Hodgson

NUCLEON transfer reactions are one of the most powerful ways of determining the properties of nuclear states, and over the years very many studies have been made of practically every nucleus in the periodic table. The one-nucleon transfer reactions are particularly useful for determining the single-particle properties of nuclei, while reactions transferring more than one nucleon provide information about their collective properties.

For practical reasons not all nucleon transfer reactions are equally easy to carry out. For example, reactions with incoming or outgoing neutrons cannot be studied with the same energy resolution as those involving charged particles. Any addition to the list of reactions available for nuclear spectroscopy is therefore most welcome, and in recent years use has been made of reactions that have unstable outgoing particles.

One of the first of these unstable particles was the nucleus ^8Be , which rapidly decays into two alpha particles. The energy of breakup is however very small, only 96 keV, so the two alpha particles are emitted in almost the same direction, and are thus easily detected. Now another such particle, the nucleus ^3He , consisting of two protons in an $^1\text{S}_0$, $T=1$ state, has been shown by a group at Berkeley to be detectable in nuclear reactions. This is important because the (α , ^3He) reaction can now be studied, and this provides a convenient

Energy spectra of ^3He nuclei from the (α , ^3He) reaction on ^{12}C (a), ^{13}C (b), and ^{16}O (c).

way of transferring two neutrons to a nucleus.

In their preliminary studies (*Phys. Rev. Lett.*, **37**, 812; 1976) they show how the ^3He nuclei can be detected by a pair of proton counters. Almost as soon as it is emitted from a reaction, the ^3He nucleus breaks up into two protons, travelling in almost the same direction, and these can almost simultaneously activate two adjacent proton counters. The number of counts from two unrelated protons is very small.

They have used this detection system to study the (α , ^3He) reaction on ^{12}C , ^{13}C , and ^{16}O and find energy spectra very similar to those found for reactions with stable outgoing particles. It is therefore possible to use it to study the structure of the residual nuclei.

Some of their spectra are shown in the figure, and it is notable that very few states are excited, showing that the reaction is very selective. This means that the reaction will only go to states of a particular structure, and this enhances its value as a spectroscopic tool.

Examination of the states excited in the reactions mentioned shows that they are all of high spin. The final nuclei are ^{14}C , ^{15}C and ^{16}O and the states excited are the 3^- at 6.73 MeV and the 4^+ at 10.55 MeV in ^{14}C ; the $5/2^-$ at 0.74 MeV in ^{14}C ; the $5/2^-$ at 0.74 MeV in ^{15}C ; and the 4^+ at 3.55 MeV in ^{16}O .

The preferential excitation of high spin states has already been observed in

the (α , d) reaction and these states are favoured because the kinematics of the reaction are such that the neutron-proton pair is easily captured into a relative triplet state about an undisturbed target core. In the same way the observed selectivity in the (α , ^3He) reaction corresponds to the capture of a neutron-neutron pair into a relative singlet state. At 65 MeV, the energy of the alpha particles used in this experiment, the angular momentum transferred in a surface reaction is about four or five units of \hbar , so that states formed by capturing the two neutrons into d orbitals with the configuration $(d_{5/2}^2)_1^+$ should be preferentially excited. The known spins of the states that are selectively excited are in agreement with this simple picture. Similar arguments can be used to predict the states that will be excited in reactions at different energies and on different nuclei.

These results already show the usefulness of the (α , ^3He) reaction in exciting states of high spin in nuclei. It is likely to be applied to study the structure of many nuclei throughout the periodic table. □

Pressure solution

from K. R. McClay

The Tectonic Studies Group of the Geological Society held a discussion meeting at Imperial College on the subject of pressure solution and Coble Creep, on November 5, 1976.

THE role of diffusive mass transfer processes in geological deformations, although indisputably important, has always been difficult to assess critically and even more difficult to quantify. Ever since Sorby, in the late 19th century, realised that some rocks exhibit textures and structures that can only be explained by 'solution' at highly stressed grain boundaries and re-deposition of minerals in less stressed regions, structural geologists have been trying to understand this phenomenon of 'pressure solution'. This rock deformation mechanism has largely been ignored since the turn of the century, and only in the 1960s was interest in pressure solution revived, chiefly by J. Ramsay.

The meeting was intended to review current research on pressure solution and diffusion processes in rocks and also to evaluate their importance in geological deformations. Although the meeting was concerned with the fundamental aspects of pressure solution processes, these are also of considerable importance in the compaction behaviour of the reservoir rocks

in some oil fields.

Flow by diffusive mass transfer involves transport of matter from grain boundaries subjected to a high normal stress to grain boundaries which are less highly stressed. If the diffusion is predominantly through the grains, the process is termed Nabarro-Herring Creep, whereas if it is predominantly around grain boundaries, the flow is called Coble Creep. In general, grain boundary sliding must occur to accommodate the grain shape changes due to diffusion. These processes only proceed at a detectable rate, when the temperature is a large fraction of the absolute melting temperature of the material. Whereas processes involving solid state diffusion probably occur in high grade metamorphic rocks and in the mantle, geologists have long recognised that textures such as tectonic stylolites, truncated fossils and tectonic overgrowths in low grade metamorphic rocks often indicate deformation by diffusive mass transfer. Even over the relatively long time available for geological deformations, solid state diffusivities would be too slow to account for the observed strains. It is therefore inferred that the rate of diffusive mass transport is enhanced by the presence of an intergranular fluid film—hence the term pressure solution. Thus Coble Creep and pressure solution are geometrically similar in that they both involve intergranular diffusion.

E. Rutter (Imperial College) demonstrated that Coble Creep and pressure solution have similar flow laws (for a review see Rutter, *Phil. Trans. R. Soc. Lond.*, **A283**, 203; 1976), and indicated that the rate of diffusive mass transfer is generally considered to be the rate-controlling step during deformation. Rutter also emphasised the importance of recognising the several possible diffusion paths in low grade metamorphic rocks (R. Knipe, Imperial College). This research indicates that in some sandstones, intracrystalline diffusion along subgrain walls may be able to give rise to strain rates equivalent to those for pressure solution along grain boundaries. Stress relaxation experiments (E. Rutter and D. Mainprice, Imperial College), clearly showed the strong influence of pore water on the creep behaviour of Tennessee sandstone. They inferred that this behaviour indicates deformation by grain boundary sliding accommodated by diffusive mass transfer. In a review of the field evidence for pressure solution (such as striped cleavage, tectonic stylolites, and truncated fossils), J. Ramsay (University of Leeds) indicated that two types of pressure solution regimes occur; an isochemical regime where precipitation of the dissolved phase occurs close to the

generating interface (giving pressure shadows and overgrowths) and a regime where the bulk chemistry is changed because the dissolved material is precipitated elsewhere (giving tectonic veining). The influence of stress 'risers' which produce variations in the mean stress was considered important in the initiation of pressure solution seams.

M. Casey (University of Leeds) has formulated a purely solid state, Coble Creep finite element model for diffusion over several grain diameters (that is, Ramsay's second regime). Applying this to a study of differentiation in microfolds and crenulations he has concluded that fluid-assisted diffusion is necessary to account for these microstructures. B. Burton (CEGB Laboratories, Berkeley) discussed the available data on Coble Creep in metals and ceramics, and emphasised that this may not be an important deformation mechanism at low stresses and low homologous temperatures because of the stress needed to create sources and sinks for vacancy diffusion.

R. De Boer (Shell Laboratories, Rijswijk) pointed out the difficulties in experimental investigations of pressure solution. The process is intrinsically slow and cannot be speeded up because of the low heat of activation, and also the difficulty in suppressing plastic deformation and cracking.

In experimental simulation of oil reservoir phenomena, he has found that pressure solution phenomena occur in quartz sands above 280 °C and in carbonate mixtures at 200 °C. An important report of recent research involving fluid inclusion geothermometry and oxygen isotope studies was

given by R. Kerrich (University of Western Ontario). He suggested that grain size greatly influences pressure solution processes and that these processes are important in the deformation of fine-grained quartz and carbonate rocks at low metamorphic temperatures. A lively discussion was generated by the contribution of A. Beach (University of Liverpool) who considered that many of the residue minerals in pressure solution seams are in fact the products of prograde metamorphism. Metamorphic reactions could produce the silica found in the tectonic veins common in low grade metamorphic environments.

Over the past decade much data has been collected and many significant advances made, and there has been a convergence towards detailed microstructural, isotopic and chemical studies of natural pressure solution systems. Although only limited success has been achieved so far in experimental work, stress relaxation tests will allow access to the slow strain rates which are not attainable in normal triaxial tests. Grain size effects are very important and careful consideration of the various possible diffusion paths must be made. Many questions still remain unanswered, however, particularly about the origin of the periodicity of pressure solution seams and striping. Many research programmes are being pursued however, and these will undoubtedly produce results which will not only be of great academic interest but also of significance in the interpretation of some fault behaviour, and compaction behaviour of oil field reservoir rocks. □

A hundred years ago

WE frequently saw table-topped icebergs with the upper surface very irregular; when that is the case evidence may usually be found from the colour, the closeness of the veining and other appearances that it is not the original surface of the iceberg which is now presented to us, but a second surface produced by cutting away by the sea of an entire story, as it were,

of the berg; which although it had no doubt at one time during the process been greatly inclined, had recovered its equilibrium on the whole of the upper layer having been more or less symmetrically removed. The Star of Bethlehem

David W. Hughes*

The Star of Bethlehem was probably a triple conjunction of Saturn and Jupiter in the constellation of Pisces, the significance of which was only obvious to the Magi of Babylonia. This occurred in 7 BC and events indicate that Jesus Christ was probably born in the Autumn of that year, around October, 7 BC.

THE Messianic star which heralded the birth of Jesus Christ and shone in the skies over Bethlehem, Judaea has been a phenomenon of considerable interest and much mystification for centuries. Almost every Christmas the star is pondered over and discussed. Invariably the same conclusions are drawn—the cause and form of the star are still uncertain. The astrologically significant triple conjunction of Saturn and Jupiter in Pisces is the most likely candidate but the two comets of March, 5 BC and April, 4 BC cannot be dismissed. Neither can the possibility that the star was simply legendary.

Biblical background

The principal account of the star is found in the gospel of St Matthew. It begins (Matthew II, 1–2):

"Now when Jesus was born in Bethlehem of Judaea in the days of Herod the King, behold, there came wise men from the east to Jerusalem, saying, where is he that is born King of the Jews? For we have seen his star in the east, and are come to worship him."

The term "in the east" in the second verse is incorrect in this Authorised Version translation^{1,2}. Originally it was written *en té anatólē* (Greek singular) whereas "the east" is usually *anatólai* (Greek plural). *Anatólē* has a special astronomical significance, indicating the earliest visible rising of a star at day break (the helical rising), and so the second verse should read "for we have seen his star appear in the first rays of dawn". These first two verses also indicate that Jesus was born and the visit of the wise men took place some time between 39 and 4 BC when King Herod was on the throne. Learning of the prophecy (Micah V, 2), "But thou, Bethlehem Ephratah, though thou be little among the thousands of Judah, yet out of thee shall he come forth unto me that is to be ruler in Israel.", Herod told the wise men that this is where Christ would be.

"Then Herod, when he had privily called the wise men, enquired of them diligently what time the star appeared. And he sent them to Bethlehem and said, Go and search diligently for the young child; and when ye have found him bring me word again, that I may come and worship him also. When they had heard the king, they departed; and lo, the star, which they saw in the east went before them, till it came and stood over where the young child was. When they saw the star, they rejoiced with exceeding great joy. And when they were come into the house, they saw the young child with Mary his mother and fell down, and worshipped him: and when they opened their treasures they presented unto him gifts; gold and frankincense and myrrh."

This second passage contains many interesting points. Very few people saw the star. Although the wise men saw it, Herod and

all Jerusalem did not, so the Christmas card image of a huge brilliant star illuminating all Bethlehem cannot be correct. It seems also that there were two separate appearances of the star. The first induced the wise men to leave the east and set out for Judaea; they then lost sight of it for a time. The second occurred when they were in Jerusalem and here it pointed out to them the place at Bethlehem where the object of their search was to be found. Not only did it point out Bethlehem, but it "went before them" and finally "stood over" Bethlehem. The star must have then been in the zenith. This ties in with the legend recounted by Maunder³. Apparently the star had been lost in the daylight by the time the wise men reached Jerusalem (indicating that it was an evening star during their journey). On reaching Bethlehem, apparently nearly at midday, one of them went to the well of the inn to draw water and, on looking down the well, saw the star reflected in the surface of the water—again indicating that it was in the zenith and that they had arrived at the right place. (For a discussion of seeing stars in wells during the day time, see refs 4 and 5.) It must be noted, however, that if a star is in the zenith it will appear to be equally over every object in the neighbourhood.

A star had been mentally associated with the coming of the Messiah for a long time. The oracle of Balaam (Numbers XXIV, 17) said,

"I see him, but not now;
I behold him, but not nigh:
a star shall come forth out of Jacob and a sceptre shall rise out of Israel."

This idea is, in fact, attributed to a man whose home was near the river (Numbers XXII, 5), that is in Mesopotamia, where there was great interest in astrology and astronomical objects and where the Old Testament would be well known and substantively the same as it is now. Some present-day scholars⁶ however think the term "star" in Numbers (XXIV, 17) applies to the Messiah himself and not to the sidereal phenomenon heralding His appearance.

The third reference to the star is not in the Authorised Version of the Bible but in one of the infancy gospels that were omitted when the Bible was compiled. The Protoevangelium of James (XXI, 2) states⁷:

"And he (Herod) questioned the wise men and said to them: 'What sign did you see concerning the new born King?' And the wise men said: 'We saw how an undescribably great star shone among these stars and dimmed them, so that they no longer shone, and so we knew that a King was born for Israel. And we have come to worship him', and Herod said: 'Go and seek and when you have found him, tell me, that I may also come to worship him'. And the wise men went forth. And behold, the star which they had seen in the east went before them, until they came to the cave. And it stood over the head of the child."

*Department of Physics, University of Sheffield, Sheffield S3 7RH, UK

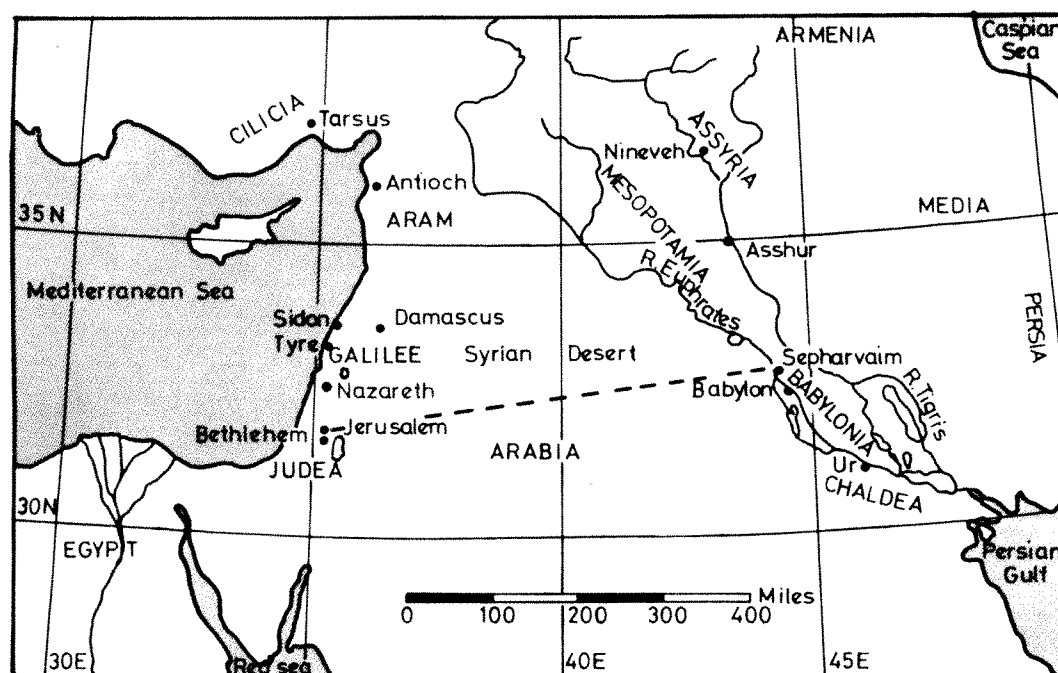

Fig. 1 The Middle East indicating one of the many possible routes of the Magi's journey from the east to Jerusalem and Bethlehem.

Here clues are given as to the star's brightness. To dim the other stars requires it to have a brightness comparable with or even brighter than the full Moon. But if this was so why didn't Herod and all Jerusalem know of it?

The wise men

The word Magi comes from the greek (μαγοι) which the Authorised Version translated as "wise men" and the *New English Bible* as "astrologers". They were probably Median priests of Zoroastrianism who, apart from performing the duties of national priesthood, used to occupy themselves with the interpretation of dreams. Babylon, Assyria and Chaldea have been put forward as their place of origin (Fig. 1). It has also been suggested that Magi does not refer to a specific race at all but is just a general name for a priestly cast of "magical" tendencies. In the earliest carvings and pictures they are shown in Persian dress, wearing trousers. It is said that such a carving saved the Church of the Nativity of Ravenna from the general havoc of the Persian onslaught in AD 614. Astrology, the prediction of future events from the positional relationship between the Sun, Moon and planets and the stellar background, was definitely one of their practices.

In the language of the Old Testament and probably St Matthew as well the term "the east" was very vague and included countries that lay considerably to the north as well as the east of Palestine. Previous biblical books (Isaiah LX, 6; Psalms LXXII, 10, 15) predicted that the kings would come from Arabia (Sheba, Seba and Tarshish). But other biblical scholars have favoured Persia, Parthia (a country south-east of the Caspian that used to extend from the Indus to the Euphrates) and Babylonia. Wherever they came from they would have been expecting that a King of the Jews was to be born and have probably learnt of this from Jewish sources. (This expectation was widespread, compare Simeon in Luke II, 25.) The nature of the gifts does not present a clue.

It was not until the sixth century that tradition changed the Magi into kings. Their number was fixed at three because of the threefold nature of their gifts (eastern tradition has it that there were twelve).

The date

In AD 525 Dionysius Exiguus, a prominent scholar and Roman monk, fixed the origin of the present calendar so that Jesus was born in December, AD 1 (anno domini, "in the year of the Lord"). AD 1 corresponded to AUC 754 in the Varronian

reckoning (AUC standing for *ab urbe condita*, from the founding of Rome). Unfortunately Exiguus forgot the year zero which should have been inserted between 1 BC and AD 1 (in fact astronomical reckoning has AD 1 = 1, 1 BC = 0, 2 BC = -1 and so on) and also the 4 yr when Emperor Augustus ruled under his own name of Octavian. So Exiguus was at least 5 yr out.

Jesus was born in the days of King Herod. According to the historian Flavius Josephus⁸, Herod died within a few days of an eclipse of the Moon visible from Jericho and a few days preceding the feast of unleavened bread. The eclipse is the only one mentioned by Josephus⁹ and must have been that which occurred during the night of March 12-13, 4 BC. Passover started on April 11, so Herod died between March 12 and April 11, 4 BC. Christ must have been born before this. In fact when Herod died Christ was in Egypt with his parents, the family having taken refuge there after being warned of Herod's impending wrath.

On realising that the Magi had not returned to Jerusalem to tell him where the child was, but had gone back to their country another way, Herod sent men to kill all the children in Bethlehem and its environs who were 2 yr old or less "according to the time which he had diligently enquired after the wise men" (Matthew II, 16), so Christ could have been anything up to 2 yr old at this time.

Luke II provides another clue about the birth date. Joseph and Mary journeyed to Bethlehem from Nazareth because Caesar Augustus decreed that all the world should be taxed. An ancient inscription unearthed in Ankara¹⁰ lists the years in which orders were issued for tax collection. The most feasible date is 8 BC, but slow travel and communications in those days could have delayed the actual collection of taxes by a year or two. Luke also states that this taxing was first made when Cyrenius (Quirinius in Latin) was governor of Syria. Quirinius was a consul in 12 BC and also fought against the Homanadensians in Cilicia before 6 BC. Tertullian¹¹ states that the census at the time of the birth of Jesus was taken by Sentius Saturninus who was governor of Syria between 9 and 6 BC. Quirinius could have been associated with Saturninus in this project some time between 6 and 5 BC, when he was an Emperor's legate in Syria. But he did not become governor of Syria until AD 6 so Luke was mistaken (II, 2). Needless to say if Luke were correct in II, 2, Christ would have been born some time between AD 6 and 7 when Quirinius governed Syria.

Some early Christian writers (Origen and Eusebius, for

example) state that Jesus was 2 yr old when the wise men came; he was then taken to Egypt and remained in Egypt for 2 yr before returning to Nazareth. St Luke mentions neither star nor Magi in his gospel but tells of the first month or so of Christ's life, of His circumcision after 8 d and of His being brought to the temple in Jerusalem after Mary's purification.

All in all the above facts indicate that Jesus was born in 6 bc but some biblical scholars, with justification, plump for 7 bc and 5 bc. A brief chronology is shown in Fig. 2.

On which day of the year was Christ born? Christmas Day, December 25, is celebrated all over the world as the birthday of Jesus but this date has only been used since about AD 336 (ref. 12). In those times this date was accepted as the time of the winter solstice, midwinter's day, after which daylength increases. The pagan feast of *dies solis invicti natalis* (the birthday of the unconquered Sun) was celebrated on that day, which occurred near the middle of Saturnalia, a season during which work ceased, houses were decorated with laurels and evergreens, gifts were exchanged and parties and processions were held. As many early Christians would not give up this pagan holiday the western Church decided to transform the pagan ceremony into a Christian festival by having Christmas Day on December 25. In the east the birth was celebrated on January 6, a date to which also the star and the Magi, the baptism of Christ and the miracle at the wedding at Cana were attached. January 6 was also the date of the festival in the temple of Kore at Alexandria and at places in Arabia, celebrating Kore, the virgin, giving birth to Aion. Again the same date could have been chosen to replace a pagan ceremony by a Christian one. Epiphanius (AD 315-403) gives January 6, AUC 752 (2 bc) as the birthday.

Clement of Alexandria in the *Stromata* (AD 194) gives November 18, 3 bc but also states that others think the birthday was either May 20 or April 19/20. Epiphanius, 120 yr later, stated that May 20 (or May 21 or June 20) were the dates of the conception and not the birth so some confusion exists here. However the dates were fixed, they seem to agree with an old

tradition that Christ was conceived in the spring and born around midwinter. Keller² introduces another interesting complication. According to St Luke (II, 8), "there were in the same country shepherds abiding in the field, keeping watch over their flock by night". The climatic conditions in what was then Palestine during Christmas time are most inclement, there being an average 6-8 inches of rain during December and January. Bethlehem is also in the grip of frost during December, January and February and no sheep would be in the fields. Flocks are usually put out to grass between March and November, the shepherds being with the flocks during the lambing season in the spring (March and April).

The star

The star must have been a fairly long lasting phenomenon, to "go before" and "stand over", which rules out transient phenomena such as fireballs and very bright shooting stars.

What of the more lasting transients such as comets and novae (discounting the fact that a brilliant comet or nova would have been seen by Herod who, according to Matthew and James, had not seen anything)? Halley's comet was first seen in 240 bc and owing to its 76-yr periodicity, reappeared in 12 bc. It was first seen about August 25 near Mu Geminorum and moved by Beta Leonis, disappearing in Scorpio about 60 d later. It was seen all over China but no report of its observation in the west has come to light. This comet is No. 51 in Williams' catalogue¹³ and is too early to be the Star of Bethlehem. No. 54 (of AD 13) is too late. This leaves No. 52 which appeared in March, 5 bc in the constellation of Capricorn and lasted 70 d, and No. 53 which appeared in April, 4 bc in Aquila and was possibly a nova being referred to in the Chinese as a "comet without a tail".

Some people think that Venus was "the star" and at the latitude of Bethlehem Venus is high enough in the sky to be a most impressive sight, being at times 15 times brighter than Sirius, the brightest star. But it is most unlikely that the Magi,

Fig. 2 A chronology of the major biblical and astronomical events occurring around the time of the birth of Christ.

constant observers of the sky, would be caught unawares by an appearance of Venus.

Another possibility is that the star was simply the conjunction between two or three planets. Two or more bright planets very close together in the sky provide a most striking sight. Johannes Kepler was fascinated by the conjunction between Jupiter and Saturn on December 17, AD 1603. In the spring of 1604 Mars moved into the vicinity of the other two and in autumn 1604 a supernova (SN 1604 Ophiuchi) appeared nearby. All in all, Jupiter and Saturn came into conjunction three times in 6 months. Jupiter and Saturn have orbital periodicities of 12 and 29 yr, respectively, so Jupiter on average passes Saturn every 20 yr. About every 120 yr, three successive conjunctions take place over about 6 months, this being known as a triple or great conjunction. Such a conjunction will occur every 120 yr and a similar one would have occurred in 7 BC. Pritchard^{14,15} confirmed this fact, and on May 29, September 29 and December 4, 7 BC a conjunction occurred in the constellation of Pisces, which is astrologically associated with the Jewish people. In February, 6 BC Mars moved into the configuration and formed an equilateral triangle with the other two planets, a situation known as a massing of planets¹⁶, but the Sun was too close for this to be observed with the naked eye.

Pritchard¹⁵ points out that in 66 BC, about two revolutions of Saturn and five of Jupiter before 7 BC, a closer single conjunction of the two planets took place, again in Pisces. In February, 66 BC the planets would set about 45 min after the Sun and would be less than 55 min of arc apart. Whether the astrological significance to the Magi of this single conjunction was the same as the significance of a triple conjunction is unknown. Maybe these previous conjunctions also impelled Magi to journey to Jerusalem, but the Bible only reported the fruitful journey.

Sinnott¹⁷ studied the 200 conjunctions and 20 multiple groupings that occurred between 12 BC and AD 70, these being gleaned from Tuckermann's book¹⁸. Sinnott concentrated on very close groupings, "weeding out" commonplace conjunctions and ones which were widely separated, and lists six conjunctions which could be seen from the Middle East in which the stars were less than 12 min of arc apart and more than 15° from the Sun (so they easily could be seen at night). These are shown in Fig. 2. Unfortunately none occurred between 12 BC and 3 BC, indicating (if the above thoughts about when Christ was born are correct) that Sinnott's selection criteria are too strict. The two conjunctions of the brightest planets, Venus and Jupiter, the first on August 12, 3 BC, visible in the eastern dawn sky from about 0345 h to 0520 h when they were separated by about 12 min of arc (in Leo, near Regulus) and a similar event on June 17, 2 BC when they were less than 4 min of arc apart and close to the western horizon where they would seem to fuse into one star "gleaming like a great beacon over Judaea to the west", would have been most impressive but do occur after Herod's death. The second conjunction again occurred near Regulus, a royal star. (Astrologically it is interesting that Judah, one of the tribes of Israel, has the lion, symbolising the constellation Leo, on its standard. Bethlehem, in the land of Judah, was the predicted birthplace of a "Governor that shall rule my people Israel" (Matthew II, 6). These facts were well known to the Magi.)

Possible sequences of events

It must be remembered that the Magi were skilled astrologers and accomplished star gazers with great knowledge of the sky, backed up by about 4,000 yr of astronomical observations. Many towns in the Middle East have legends retelling how theirs was the town from which the Magi started on their journey (the people of Saveh in Persia told Marco Polo that their town was the starting point). The triple conjunction of 7 BC had been predicted. The calculations and predictions are given in an almanac found on a cuneiform tablet at Sippar (Sepharvaim) in Babylonia, a town noted for its school of

astrology. The conjunction took place in Pisces, a constellation which is astrologically associated with the Jewish people and Israel (compare the writings of Rabbi Arbarband 1437–1508). The Sun moves through Pisces at the boundary between winter and spring and astrologically this indicates the end of an old age and the start of a new one. Jupiter was considered to be a lucky and royal star and in traditional Jewish astrology Saturn protected Israel.

Babylonian astrologers steeped in Jewish tradition would have predicted the triple conjunction in Pisces. Realising its astrological significance (that is, a Jewish king born in Israel) and remembering the prophecy of Balaam (Numbers XXIV, 17) and seeing in the sky their astronomical prediction come true would be ample justification for starting a journey to pay homage to the new king, the herald of a new age.

The journey from Sepharvaim to Jerusalem across the Arabian desert is about 550 miles. Preparing for and taking this journey would take about 4 months. The planetary clustering would have begun about the end of February, 7 BC with Jupiter moving from Aquarius towards Saturn in Pisces. As the Sun was also in Pisces at this time the planets would not be visible. Not until April 12 did both planets rise helically in Pisces (compare Matthew II, 2). The first close encounter (0.98 degrees separation—twice the diameter of the full Moon) took place on May 29 and was visible for about 2 h in the morning sky. The Magi could have set out towards the end of June, 7 BC, the September 29 conjunction confirming their predictions as they were nearing Jerusalem and the December 4 conjunction, occurring after the audience with Herod, pointing the way south to Bethlehem 5 miles away. Pisces rises at about 0200 h, 2200 h, 1900 h and 1200 h during May, July, September and December, indicating that the two planets would be clearly visible during their journey. The planets are due south (and closest to the zenith) about midnight during September and at about 1900 h during early December. (This throws doubt on to the Maunder legend of the midday star in the well.) Jesus could have been born about 2 months before the last conjunction, say in early October, 7 BC. He would have been circumcised at 8 d, then after the 33 d of Mary's purification taken to Jerusalem where a sacrifice was made. After returning to Bethlehem he was visited by the Magi. (The word *τοπαῖδν* in Matthew II, 11 means "a very young child" or infant.) After being warned in a dream about Herod's impending wrath, Joseph fled with Mary and Jesus to Egypt. In early October the shepherds could be moving the sheep from the hills to their winter quarters. Jesus would have been 2.5 yr old when Herod died.

A second scenario could be as follows. The conjunctions of 7 BC could simply have attracted the wise men's attention towards Palestine, the comet of March, 5 BC starting them on their journey. They would have arrived well before Herod's death (which occurred between March 12 and April 11, 4 BC) and being told that Jesus was born in Bethlehem, arrived there about April, 4 BC when the nova was shining. Before Herod died he ordered that all children under 2 yr old be killed, and with this scenario the order would have gone out just before he died, giving Joseph, Mary and Jesus time to flee to Egypt.

Jesus would have been about 2 yr old when this order went out and when seen by the wise men. This ties in with Epiphanius* who stated that the star shone in the east 2 yr before the Magi arrived in Jerusalem. So Jesus would have been born in the spring of 6 BC, Epiphanius's star could have been the conjunction and the shepherds would have been in the fields at lambing time.

But why should Joseph and Mary stay in Bethlehem for 2 yr when they had only gone there to be taxed? And why had not Herod and the Jews connected the comet of 5 BC with the coming of Christ? It is possible that Herod missed the triple conjunction when the planets only just came within 1° of each other. The Protoevangelium of James supports this latter picture.

Non-astronomical possibilities

One easy way out of the dilemma introduced by the Star of Bethlehem is to regard it as another miracle, as the direct intervention of the hand of God and thus as a phenomenon not requiring a scientific explanation.

It could also just be a legend. No king worth his salt in those days was born without some celestial manifestation. A star greeted the birth of Mithridates (131–63 BC) and Alexander Severus¹⁹. The temple of Diana at Ephesus was burned down the night that Alexander the Great was born, Magi announcing that the plague and bane of Asia had been born that night. The magos Tiridates and some followers came to Rome to acknowledge the divinity of Nero in AD 66.

Matthew, who wrote his gospel for a Jewish audience and who frequently cited passages of the Old Testament to prove points to his readers, probably felt that a star was necessary to fulfil the prophecy of Balaam. The Essenes, who studied the prophets to find interpretations of the contemporary scene, would believe that such a prophecy could not have been without fulfilment. They would go so far as to say: no star, no messiah. The absence of the Matthean clause "that it might be fulfilled" is very worrying and casts doubts as to how far the evangelist regarded the account of the star as historical. Albright and

Mann¹ suggest that the clause might have been "edited out" of Matthew's gospel at a later date to appease Gnostic opposition to the church. (The gospel of St Matthew was probably written some time between AD 65 and AD 85.)

Bearing in mind Herod's surprise on being told of the star by the Magi, the triple conjunction in 7 BC seems to be the most probable candidate. If this is so Christ would have been born in about October of that year.

Nuclease cleavage of chromatin at 100-nucleotide pair intervals

Werner Altenburger, Wolfram Hörz & Hans G. Zachau

Institut für Physiologische Chemie, Physikalische Biochemie und Zellbiologie der Universität München, FRG

Digestion of mouse liver nuclei with DNase II leads to a novel cleavage pattern with a 100-nucleotide pair periodicity. From chromatin, this pattern or the standard 200-nucleotide pair repeat can be produced depending on the ionic conditions. The results are interpreted by assuming different conformational states of the nuclear material, including condensed and extended forms.

THE discovery of a chromatin subunit has had a great impact on the concept of the structure of chromatin (for reviews see refs 1–3). Evidence for this subunit, which has also been termed ν -body or nucleosome rests mainly on results obtained from nuclease digestion of nuclei and on direct visualisation of particulate structures in the electron microscope. Approximately 200 nucleotide pairs of DNA seem to be wrapped around a globular histone bead which has been proposed to consist of two of each of the histones H2A, H2B, H3 and H4. Digestion of nuclei with an endogenous nuclease or micrococcal nuclease yields protected DNA fragments of 200 nucleotide pairs and multiples thereof, presumably by attack in a region between the subunits. Within the nucleosome, cleavage at preferred sites has been reported for micrococcal nuclease¹ and for DNase I which introduces single-strand nicks at intervals of ten nucleotides into the nucleosomal DNA².

We have studied various aspects of chromatin structure with the help of restriction nucleases³ and by a detailed investigation of the action of micrococcal nuclease^{7,8}. It seemed promising to extend the work to DNase II which has already been used in a few laboratories to digest chromatin^{9–11}. We have used this nuclease for several reasons: it introduces into DNA single-strand as well as double-strand breaks¹², it has no requirement for divalent cations in contrast to all other nucleases used for the digestion of chromatin, and even though its pH optimum is around 5, it retains sufficient activity at neutral pH to permit its use in physiological conditions¹². One unexpected outcome of our experiments was the finding that DNase II can cleave the DNA in chromatin and nuclei with a previously unobserved 100-nucleotide pair periodicity.

100-Nucleotide pair repeat pattern from mouse nuclei

Mouse liver nuclei were treated with DNase II and the DNA was analysed by Agarose gel electrophoresis. The resulting pattern is shown in Fig. 1, together with the pattern found with micrococcal nuclease in the same conditions. The positions of the peak maxima in the DNase II pattern correspond to sizes which are multiples of 100 nucleotide pairs (Fig. 1B), that is half the value obtained with micrococcal nuclease. The gradual shortening

Fig. 1 Digestion of mouse liver nuclei with DNase II and micrococcal nuclease. Mouse liver nuclei were prepared as described before⁶. Samples containing 100 μ g of DNA were suspended in 10 mM Tris-HCl, pH 7.0, 1 mM phenylmethane sulphonyl fluoride (PMSF) in a total volume of 0.2 ml. Microscopic inspection showed the nuclei to be largely intact in these conditions. **A**, Incubations were for 1 h at 37 °C. In (b) and (c) micrococcal nuclease (Worthington) was present at concentrations of 7 and 25 U ml⁻¹, respectively, and the incubation buffer was supplemented with 1 mM CaCl₂. In (d) and (e) DNase II (Worthington) was added to concentrations of 125 and 250 U ml⁻¹, respectively. Slot (a) contains a mouse satellite DNA marker partially digested with *Eco*RII¹³. After incubation, DNA was extracted as described before⁶ and 5 μ g was applied to a 1.8% vertical Agarose slab gel, run in the Tris-borate buffer system as described before¹⁴. It was afterwards stained with ethidium bromide (1 μ g ml⁻¹) for 30 min. **B**, DNA from nuclei incubated with DNase II (250 U ml⁻¹) as in (A) was electrophoresed in a 1.8% Agarose gel with and without admixed mouse satellite DNA, partially digested with *Eco*RII. The gel was stained with ethidium bromide and photographed, and the negative was scanned as described before⁶. The lower tracing shows the DNase II pattern: in the upper tracing DNA from a micrococcal digest of nuclei is shown for comparison. Inset, average sizes of the DNase II fragments are depicted as they are determined in the coelectrophoresis with the satellite DNA digest. The molecular weights of the satellite fragments had been determined (R. E. Streeck, to be published) relative to the size of the sequenced restriction nuclease fragment H of SV40 virus (ref. 15 and W. Fiers, personal communication).

of the DNA fragments during digestion with micrococcal nuclease was not observed with DNase II. This may explain why the fragments in the DNase II digests seem to be slightly larger than the corresponding fragments from micrococcal nuclease digests (Fig. 1). A kinetic analysis of DNase II digestion (Fig. 2) indicates that the 100-nucleotide pair repeat is present as soon as discrete bands can be resolved, and persists throughout digestion.

To rule out the possibility that the 100-nucleotide pair periodicity might appear only in rather special conditions of digestion and possibly be due to a minor activity present in the commercial enzyme preparation used, we tested a wide range of incubation conditions. The intensity of the bands relative to the background turned out to be highest in the low ionic strength conditions used. The bands were also detectable, however, when nuclei were digested in the presence of up to 5 mM EDTA or 5 mM CaCl₂ or up to 150 mM NaCl. Concentrations of CaCl₂ or EDTA in excess of 10 mM prevented degradation altogether. Variation of the pH between 4.0 and 7.5, and a change to phosphate and acetate buffers, did not abolish the pattern. It was found reproducibly with several batches of DNase II as well as with a preparation of DNase II prepared in the laboratory of G. Bernardi¹². The pattern is also not an exclusive property of mouse nuclei since it was found with rat liver^{7,8} as well as calf thymus nuclei (M. Steinmetz, R. E. Streeck and H.G.Z., manuscript in preparation).

It is impossible to differentiate quantitatively between DNA falling into the 100-nucleotide pair repeat pattern and randomly cleaved DNA which contributes to the background in the gels. Therefore we cannot rule out the possibility that only a certain part of the nuclear material is cleaved with a 100-nucleotide pair periodicity in these experiments.

Fig. 2 Kinetics of digestion of mouse liver nuclei with DNase II. Nuclei were digested with DNase II (120 U ml⁻¹) as described in Fig. 1. Samples containing 5 μ g of DNA were withdrawn after 5 (a), 8 (b), 11 (c) and 18 (d) min, and analysed on a 1.8% Agarose gel. The molecular weight scale (in nucleotide pairs) was derived from *Eco*RII-digested mouse satellite DNA (Fig. 1).

Protease activity, as one potential source of artefact, was monitored during DNase II action by analysis of the histone patterns. In the presence of PMSF, which was always used, no differences were observed between unincubated samples and samples incubated without enzyme, with DNase II, and with micrococcal nuclease for the incubation periods used.

DNase II resembles DNase I in its ability to introduce single-strand nicks at 10-nucleotide intervals into the DNA. In denaturing 6% polyacrylamide gels¹⁶, DNA from DNase II-digested nuclei gave a series of strong bands with a 10-nucleotide repeat up to a fragment of 180 nucleotides, similar to the pattern found with DNase I⁵. In addition, broader bands were present at 200, 300, 400, 500 and 600 nucleotides.

New chromatin subunit?

Nucleosomes can be isolated as deoxyribonucleoprotein particles by sucrose gradient centrifugation. It was conceivable, therefore, that by this technique discrete deoxyribonucleoprotein particles containing 100-, 200-, 300-, and so on, nucleotide pair DNA, could be observed after digestion with DNase II. Figure 3 shows that this is not the case in the conditions used, but that instead particles are seen which correspond in their sedimentation properties to those produced with micrococcal nuclease.

Quantitatively, however, the patterns do differ. In the DNase II digests, there is always, even after extensive digestion, little material in the monomer region and the peaks with even numbers are more pronounced than the others. If the DNA from the gradient fractions is analysed in Agarose gels (Fig. 3B) it is evident that this DNA is of the 100-nucleotide pair repeat type, but the rapidly sedimenting material contains not just the high multiples of the repeat unit but the entire spectrum of bands starting with the 100-nucleotide pair fragment. We interpret this to mean that one site of attack for DNase II is between nucleosomes, and that cleavage at the second site, within the nucleosome, does not lead to the appearance of a smaller particle, but that instead the integrity of the subunit is maintained. In addition, the small amount of monomeric nucleosomes and the high proportion of dimers and tetramers in the sucrose gradients indicate that these nucleosomes have a high tendency to remain associated even when the internucleosomal DNA is broken.

Histone H1 is implicated in internucleosomal interaction and might be responsible for aggregation between nucleosomes. To test this, H1 was dissociated by 0.6 M NaCl after DNase II digestion. This changed the sucrose gradient profile drastically (Fig. 4A). Much more monomer was produced at the expense of higher multiples, and the DNA analyses of the gradient fractions indicate that the aggre-

Fig. 3 Sucrose gradient fractionation of nuclease digests of mouse liver nuclei. Nuclei were isolated as in Fig. 1, except that 0.2% Triton X-100 and 1 mM PMSF were included in the homogenisation medium. They were digested with DNase II (120 U ml^{-1}) for 60 min at 37°C in 10 mM Tris-HCl, pH 7.0, 1 mM PMSF or with micrococcal nuclease (10 U ml^{-1}) in identical conditions except that 1 mM CaCl_2 was present during incubation. At the end of the incubation 2 mM EDTA was added, and the mixtures were centrifuged at low speed ($4,000g$, 10 min). The pellet was resuspended in 0.2 mM EDTA, pH 7.0, insoluble material was removed by a low speed spin and the supernatant was applied to isokinetic sucrose gradients containing 1 mM EDTA, pH 7.0 ($C = 5\%$, particle density 1.51, ref. 17). This supernatant contained negligible residual DNase II activity as shown by control incubations of the supernatant at 4°C for 24 h. Centrifugation was in a Spinco rotor SW 41 for 13 h at 38,000 r.p.m. at 4°C . The gradients were fractionated from bottom to top as described¹⁷ and absorbance at 260 nm was monitored in a flow-through cell with a Zeiss spectrophotometer. A, DNase II digest; C, micrococcal DNase digest. The numbers refer to monomeric (1), dimeric (2) and so on nucleosomes. DNA was isolated from the nucleosome fractions of both gradients and analysed on 1.8% Agarose gels (B and D) as described in Fig. 1. The solid lines correlate the nucleosome peak fractions with the corresponding DNA samples. The molecular weight scale (in nucleotide pairs) was derived from *EcoRII*-digested mouse satellite DNA (Fig. 1).

Fig. 4 Sucrose gradient analyses of nuclease digests after exposure to 0.6 M NaCl. The same nucleosome-containing supernatants as those from Fig. 3 were made 0.6 M in NaCl and then analysed as described in Fig. 3 without inclusion of NaCl in the gradients. *A* and *B*, DNase II; *C* and *D*, micrococcal nuclease digests. Slots (*f*) and (*r*) contain *Eco*RII-digested mouse satellite DNA.

gation between nucleosomes was strongly reduced (Fig. 4*B*). Nevertheless, the integrity of the nucleosome was maintained in spite of the internal cut. There is also aggregation between nucleosomes in micrococcal nuclease digests which

is abolished by exposure to 0.6 M NaCl. This is not so apparent from the sucrose gradient profiles (Figs 3*C* and 4*C*), but clearly seen in the gel analyses of sucrose gradient fractions (Figs 3*D* and 4*D*). In both micrococcal nuclease and DNase II digests nucleosomes sediment more slowly after exposure to 0.6 M NaCl, indicative of the loss of histone H1 and possibly a conformational change in the nucleosomal arrangement produced by the salt step.

DNase II digestion patterns sensitive to ionic environment of chromatin

For some experiments chromatin was prepared from the nuclei as a first step towards a more defined system. Mouse liver nuclei were suspended several times in 20 mM EDTA, 80 mM NaCl, pH 6.3 (ref. 18), and then in the usual 10 mM Tris-HCl (pH 7.0) and 1 mM PMSF. The unsheared gel-like material gave the typical pattern after digestion with micrococcal nuclease (Fig. 5*b*). The pattern obtained with DNase II from this chromatin depended very much on the ionic conditions. In the standard buffer, the DNA was cleaved by DNase II into a 200-nucleotide pair repeat pattern (Fig. 5*c*) similar to the micrococcal nuclease pattern. The 100-nucleotide pair repeat pattern

Fig. 5 Digestion of mouse liver chromatin with DNase II and micrococcal nuclease. Chromatin was prepared by extracting mouse liver nuclei three times with 80 mM NaCl, 20 mM EDTA, pH 6.3 (ref. 18). The resulting chromatin was washed twice in 10 mM Tris-HCl, pH 7.0 and digested in the same buffer in the presence of 1 mM PMSF for 40 min at 37 °C. Additions were: *a*, 1 mM CaCl_2 ; *b*, 1 mM CaCl_2 , micrococcal nuclease (25 U ml^{-1}); *c*, DNase II (500 U ml^{-1}); *d*, 1 mM CaCl_2 , DNase II (500 U ml^{-1}); *e*, 150 mM NaCl, DNase II (500 U ml^{-1}). Slot (*f*) contains an *Eco*RII digest of mouse satellite DNA (Fig. 1).

Fig. 6 DNase II digestion of a trimeric nucleosome fraction from a micrococcal digest. The micrococcal digest of nuclei was prepared and fractionated on sucrose gradients as described in Fig. 3. The material corresponding to trimeric nucleosomes was collected, concentrated and adjusted to 0.2 mM EDTA, pH 7.0, by pressure dialysis (Amicon), recentrifuged in a sucrose gradient as before and concentrated again by pressure dialysis. It was then incubated in 10 mM Tris-HCl, pH 7.0, 0.2 mM EDTA and 1 mM PMSF for 5 min without (*A* and *B*) and with DNase II (90 U ml⁻¹) (*C* and *D*). The incubation mixtures were analysed in sucrose gradients containing 1 mM EDTA, pH 7.0, in a Spinco rotor SW 56 for 14 h at 32,000 r.p.m. at 4°C. In (*A*) and (*C*) the gradient profiles are shown, and in (*B*) and (*D*) analyses of the DNA from the gradient fractions as correlated by the solid lines.

appeared, however, if DNase II digestion was carried out after prior addition of divalent or monovalent cations (Fig. 5*d* and *e*). This shift from a 200-nucleotide pair to a 100-nucleotide pair pattern coincides with strong contraction of chromatin known to be caused by these salt conditions¹⁰.

200-Nucleotide pair repeat pattern with DNase II

Cleavage at 200-nucleotide pair intervals by DNase II at low salt conditions might take place at either the inter- or the intranucleosomal sites. To decide between the two possibilities, sucrose gradient analyses and codigestion experiments were carried out with micrococcal nuclease.

Sucrose gradients of DNase II digests, which on deproteinisation yielded the 200-nucleotide pair repeat pattern, gave the standard nucleosome pattern (not shown), as would have been expected only if cleavage had occurred between nucleosomes. To define this region further relative to the region where micrococcal nuclease cleaves, trimeric nucleosomes were isolated by sucrose gradient centrifugation from a micrococcal nuclease digest of mouse liver nuclei and further digested with DNase II. In standard conditions, without any salt added, dimeric and monomeric nucleosomes were produced, containing only DNA fragments of the 200-nucleotide pair repeat length (Fig. 6). This proves that the regions cleaved by micrococcal nuclease and by DNase II in these conditions must overlap either completely or at least partially.

To find out whether DNase II digestion of trimeric nucleosomes also depends on the ionic conditions, digestion was carried out in the presence of CaCl₂ or MgCl₂ at concentrations between 0.5 and 2 mM (ref. 8). The patterns were clearly different when divalent cations were present: there were DNA bands in the gel at 200 and 400 nucleotide pairs and there was also DNA migrating in between these bands with indications of bands around 300 and 500 nucleotide pairs. The patterns were not sufficiently defined, however, to identify them clearly as of the 100-nucleotide pair repeat type.

Analogous results were obtained with two other nucleosome fractions, one containing tetramers, the other pentamers to dodecamers. Clear 200-nucleotide pair repeat patterns were seen after digestion with DNase II in standard conditions and a high background and indications of intermediate bands when divalent cations were present in the incubations.

DNase II and structural features of the nucleosome

The major difference between DNase II and other nucleases is the preferential double-strand cleavage at one site within the nucleosome. This difference might be due in part to the ability of DNase II to introduce both double-strand and single-strand cuts with high frequency¹².

It is conceivable that double-strand cleavage in the nucleosome occurs more easily after several primary single-strand cuts. At one site, cleavage would then occur in both strands. The stronger propensity of DNase II to nick DNA intranucleosomally might also be responsible for the high background of DNA in the digestion patterns. This interpretation is supported by the finding in our laboratory that DNase I, a nuclease which introduces predominantly single-strand cuts into DNA, also produces a 100-nucleotide pair repeat pattern, albeit much weaker and with an even higher background of DNA between bands⁸. That DNase I has a preferred site of attack within the nucleosome has been proposed on the basis of a strong subnucleosomal band in denaturing polyacrylamide gels²⁰.

What features of the chromatin structure lead to DNase II cleavage at the intranucleosomal site? Splitting at this site is symmetrical as far as the DNA is concerned, and in view of the symmetrical construction of the nucleosome from two of each of the core histones, it is tempting to think that DNase II might split at a site of symmetry within the nucleosome. Several models for the nucleosome structure incorporate such a symmetry element (for example refs 21 and 22). Extending the symmetry to include histone H1 would require two molecules of H1 per nucleosome. This would be appealing, but is not essential for the concept of DNase II cleavage at a site of symmetry.

DNase II as a probe into conformational states of chromatin

In chromatin, the accessibility of the intranucleosomal cleavage site to DNase II correlates with a reversible transition from an extended to a condensed conformational state. In addition to the ionic environment, temperature has been found to affect the conformational state: splitting at the second site is virtually absent at 0 °C in nuclei but the accessibility increases with temperature until, at 37 °C, both sites are cut equally well^{7,8}. In the presence of divalent cations, the temperature effects are not observed⁷. H1 is known to be involved in salt-induced aggregation of chromatin. H1-depleted calf thymus chromatin appears to have lost the intranucleosomal cleavage site, and this suggests that H1 is involved in the shift from the 200-nucleotide pair to the 100-nucleotide pair repeat pattern

(M. Steinmetz, R. E. Streeck and H.G.Z., manuscript in preparation).

Isolated oligomeric nucleosomes still have the ability to respond to ionic changes in DNase II digestion. They should therefore provide a system in which to study the parameters involved in this response. Detailed information on the effect of size and concentration of the isolated nucleosomes might tell to what extent aggregation or internal structural rearrangements of the nucleosome play a role. The results obtained with chromatin likewise do not enable us yet to decide if the opening and closing of intranucleosomal cleavage sites is due to conformational changes within the individual nucleosome or if it is the result of defined interactions between nucleosomal arrays, perhaps leading to a higher order packing of the chromatin fibril. It is clear, however, that nuclease digestion experiments can yield information not only on basic structural aspects but also on conformational states of nucleoproteins possibly related to higher structural orders.

We thank Professor G. Bernardi for a sample of DNase II. The work was supported by Deutsche Forschungsgemeinschaft and Fonds der Chemischen Industrie.

Thermal denaturation profiles and the structure of chromatin

D. Z. Staynov

Institute of Biochemistry, Bulgarian Academy of Sciences, 1113 Sofia, Bulgaria

Analysis of the melting profile of DNA stripped of non-histone proteins and histone H1 allows definite structural conclusions to be drawn; conversely, it is possible to calculate what a particular chromatin model's melting curve will look like.

shown here that the shape of the melting profile can be calculated for a given model of the chromatin structure, and conversely that explicit structural conclusions can be drawn from the observed melting curves.

Theoretical considerations

The theoretical analysis makes use of the statistical mechanics of helix-coil transitions of two-stranded polynucleotides⁷. Neglecting the generally small effect of local heterogeneity of composition, one may divide the DNA helices into four classes, in respect of melting behaviour. These are illustrated in Fig. 1a and comprise (1) helix with free ends (*o,o*-helix), (2) helix joined at both ends to more stable helices (*h,h*-helix),

OPTICAL melting profiles of intact and partially stripped chromatin have been studied in many laboratories¹⁻⁵, and have been resolved into separate transitions, associated⁶ with free DNA and the DNA helices complexed with protein. It is

Fig. 1 *a*, Thermodynamically distinguished helix types: *o,o*, *h,h* and *l,l*-helices. *b*, Relationship between melting temperature T_m and helix length N , for helices of *o,o*-, *h,h*- and *o,h*-type respectively.

(3) helix with one end free and the other joined to a more stable helix (*o,h*-helix), (4) helix between two loops, consisting of less stable, melted helices (*l,l*-helix). We now consider how the melting temperatures (T_m) of such helices depend on their lengths. Helices of the *o,o*-type have been fully treated^{8,9}; the T_m falls in a known manner with decreasing length. For an *h,h*-helix, on the other hand¹⁰, T_m rises with decrease in helix length. The other two types of helix have not previously been treated. The statistical mechanical analysis is given later.

The results are as follows: the melting of an *o,h*-helix is independent of its length; for an *l,l*-helix the situation is more complex; the relation between T_m and chain length depends on the size of the nucleotide loops at the ends. In the limit of zero loop length the configuration becomes equivalent to an *h,h*-helix, and as the loop grows, the T_m drops. It follows from the partition function (see statistics) that the T_m of an *l,l*-helix may be higher or lower than that of an infinite helix, but is always higher than that of an *o,o*-helix of the same length. The laws governing the melting of different types of helix are shown in Fig. 1*b*. A precise quantitative analysis is limited by lack of information about the magnitude of the helix initiation constant, σ , at low ionic strengths. At this stage therefore, only a semi-quantitative interpretation of the melting profiles can be attempted.

Chromatin models

The current view of chromatin structure¹¹⁻¹⁵ is based on a repeating unit of about 200 base pairs, 140 of these being in the form of a complex with protein (nucleosome), and the remaining 60 of a spacer of free DNA. On treatment with 0.6 M NaCl, the non-histone proteins and histone H1 are lost, but the periodic structure remains. In this material, called DNP 0.6, the nucleosomes contain only DNA and eight histone molecules, most probably two copies of each remaining species¹⁶⁻¹⁸.

We now consider the predicted melting behaviour of two possible models for DNP 0.6.

- **Equally Spaced Nucleosomes.** If the nucleosomes are all identical and spaced at equal intervals along the DNA, a melting profile encompassing three transitions is to be expected: that of naked DNA at the ends of the molecule (*o,h*-helices) with T_m as for free DNA (T_m^0); that of free DNA between nucleosomes (*h,h*-helices), with (as noted by Subirana³) $T_m > T_m^0$; and that of the nucleoprotein complex, which is associated with a higher numerical enthalpy of transition, both because of electrostatic stabilisation of the charged structure and the nature of the helix (*l,l*). The corresponding T_m will be higher than that of simple nucleosomes, in which the DNA has free ends. If the T_m of the second transition is sufficiently high, the second and third transitions may be brought into coincidence.

Fig. 2 Schematic derivative melting profile for a DNA duplex: *a*, with nucleosomes equally spaced along its length; and *b*, with randomly distributed nucleosomes; *c*, experimental profiles for DNP 0.6; and *d*, for the same material after sonication for 8 min at 1.2 A in an MSE sonicator. The DNP 0.6 was obtained from salt-extracted chromatin²⁰ after treatment with 0.6 M NaCl and chromatography on a Sepharose 4B column, 40×4 cm. Thermal denaturation profiles were measured in 0.25 mM Na EDTA, pH 8.0, with an instrument previously described^{21,22}. Differentiation was performed graphically, for intervals of 4 °C. The arrow corresponds to T_m for free DNA.

The breadth of the transitions will in the first place reflect the compositional heterogeneity of the duplex. The first and second transitions will in addition be broadened because of the finite lengths of the cooperative units, whereas the third phase (140 base-pair helix) should not be subject to broadening, and will resemble in shape the melting of free DNA. The areas under the peaks in the derivative melting curves will reflect the relative concentrations of the three types of structure. The predicted melting profile of this model for DNP 0.6 is shown in Fig. 2a.

• Randomly Spaced Nucleosomes. If alternatively the nucleosomes are randomly distributed along the DNA, the transition profile will be different (Fig. 2b). The second transition will be replaced by a continuous spread of melting of naked DNA. Segments short enough to have an intrinsic T_m greater than that of the nucleosomes will melt with the latter, since this implies a switch from h,h to l,l character, and the area under the corresponding peak in the derivative melting profile will be greater than would correspond to the DNA content of the nucleosomes. The third peak will be broadened by the distribution of loop lengths.

Analysis of melting profiles

The melting profile for DNP 0.6 is shown in Fig. 2c. There are four peaks, the three highest ($T_m = 61, 72$ and 82°C) corresponding to the most prominent components in whole chromatin, whereas the lowest ($T_m = 56^\circ\text{C}$) has no counterpart in chromatin. The areas under the peaks corresponding to the two highest temperature transitions correspond to the total protein content (see also ref. 3). Thus the first two transitions represent the melting of free DNA, and the other two that of complexed DNA. The first transition is broadened relative to that of free extracted DNA. The fourth is unchanged, and the second and third also do not seem to be significantly broader.

In analysing these curves we note first that there is no component of $T_m = T_m^0$, so that the amount of terminal naked

DNA is negligible. The presence of two peaks of melting of naked DNA with $T > T_m^0$ implies two populations of spacers (h,h -helices) between nucleosomes. The first and second transitions correspond to long and short segments of DNA helix respectively. The two transitions of protein-DNA complexes are sharp, and evidently represent standard, effectively homogeneous, populations containing relatively long segments of DNA with nucleotide distribution not significantly different from that of the whole DNA. Three possible reasons for the existence of these two latter (l,l -helix) transitions may be envisaged: (1) the presence of two regions differing in thermal stability within each nucleosome, (2) the existence of both long and short spacer regions between the nucleosomes; the latter would melt at temperatures determined by the length of the spacers which define the loop sizes, (3) the existence of two structurally distinct types of nucleosome.

We have found (to be published) that the relative areas under the two peaks in question depend strongly on the ionic strength, the sum of the two remaining constant.

This observation renders the first explanation improbable. It has been reported¹⁹ that mononucleosomes prepared by limited enzyme digestion melt in a single phase with a $T_m = 76^\circ\text{C}$; this is between the T_m values of the two l,l transitions. Since a l,l -helix necessarily melts at a higher temperature than the same helix in a o,o situation, the material melting in the 72°C peak cannot represent the same type of structure as that melting in the 82°C peak if both are normal nucleosomes. We therefore rule out the second explanation, to be left with the third.

The analytical procedures described above are strengthened by data obtained with ultrasonically fragmented material (Fig. 2d). The following features stand out:

• A new peak with $T_m = T_m^0$ (47°C) appears, which accounts for the melting of more than half the naked DNA. Thus the sonic fragments are short, consisting mainly of one to three nucleosomes.

Statistical mechanical analysis

The partition function Z for the ensemble of partially melted configurations of a double helix of N base pairs, in general depends on s the equilibrium constant for the addition of a base pair to the end of a helical region and σ the nucleation constant. In terms of the zipper model, whereby we ignore configurations with more than one helical region, we may write

$$Z(N) = \sum_{n=0}^N s^n w_n \quad (1)$$

where w_n is the statistical weight of configurations with n base pairs. The fraction of possible base pairs that are intact may then be written

$$f = \frac{1}{N} \frac{d \ln Z}{d \ln s} = \frac{\sum_{n=0}^N n s^n w_n}{\sum_{n=0}^N s^n w_n} \quad (2)$$

For helices in the o,h situation, w_n is unity for all N , since we assume that melting proceeds from one end of the helix only.

At the melting temperatures (T_m), $F_{o,h} = \frac{1}{2}$, and it may be shown that this occurs at $s = 1$; thus for o,h helices T_m is independent of N .

For helices in the l,l situation there are $N-n+1$ ways in which the helix of n base pairs may be situated between the two loops. We assume that the two loops contain L_1 and L_2 nucleotides and write $L_1 = 2(N_1+1)$ and $L_2 = 2(N_2+1)$.

Each of the $N-n+1$ configurations must be weighted according to the probability of ring closure. An approximation⁶ gives L^{-c} , where c is a constant, as the appropriate weight for a loop of L nucleotides. It then follows that

$$w_n = \sigma \sum_{k=1}^{N-n+1} \left[4(N_1 + N - n + 2 - K)(N_2 - K) \right]^{-c} \\ \text{for } 1 \leq n \leq N - n + 1 \\ = 2^{-c}(N_1 + N_2 - N + 1)^{-c} \text{ for } n = 0$$

This expression may be substituted into equation (2) to yield $f_{l,l}$, which is clearly dependent on N , N_1 , N_2 , s and σ .

In the event that $L_1 = L_2 = 0$, however, the situation approximates to that of a h,h -helix (melting from both ends), and in the limit of very large L_1 and L_2 it approximates to the o,o situation. We therefore suppose that the plot of T_m versus N for a l,l -helix with finite loops would lie between the curves for h,h and o,o helices, at a position depending on the size of the loops. Consequently at constant N , T_m decreases with increasing size of the loops. It then follows that the T_m of finite helices in the l,l situation can be higher or lower than that of an infinite helix, but is always higher than the T_m of a helix of the same length but in the o,o situation.

• Concomitantly the other peaks associated with naked DNA decrease, showing that the intact DNP 0.6 contained no short segments of naked DNA, for otherwise sonication would have brought about an increase in the low-melting peaks.

• The peak of $T_m = 72^\circ\text{C}$ is shifted to lower temperatures by about 2.5°C , while the peak of $T_m = 82^\circ\text{C}$ is diminished by two-thirds in amplitude. At the same time a new peak appears at 76°C . The latter presumably corresponds to mononucleosomes²⁰. The transition at 82°C arises from the melting of nucleosomes in long fragments (*I,I*-helices), and that at 76°C from nucleosomes with free ends (*o,o*-helices). The peak at 72°C cannot be identified with a nucleosome in any state. It is present in DNP 0.6 but not in enzymically derived mononucleosomes. It may represent an altered or denatured nucleoprotein structure, which is not resistant to enzymic attack.

It is hoped to extend the quantitative scope of the analysis by determining the helix initiation constant, σ , at low ionic strength, which would allow a rather precise analysis of the lengths of the naked DNA segments in chromatin, and the evaluation of the thermodynamic characteristics of the nucleoprotein complexes.

The analyses of the melting profiles of DNP 0.6 allow the following conclusions to be drawn with considerable confidence: (1) DNP 0.6 consists of a long DNA molecule containing DNA-protein complexes separated by regions of naked DNA. (2) The melting temperatures of both naked DNA segments and DNA-protein complexes are not governed solely by their intrinsic thermodynamic characteristics (mean enthalpy and entropy), but depend strongly and in an interpretable manner on their lengths and positions in the structure. Earlier simplistic

interpretations of multi-phase transitions can no longer be sustained. (3) The melting transitions of naked DNA and of protein complexes (first two and second two peaks respectively) are completely separate. (4) The distribution of the nucleosomes along the DNA is independent of local nucleotide composition. (5) The material contains two different populations, each effectively homogeneous, of DNA-protein complexes, differing from each other in thermal stability and the mean lengths of the associated DNA.

I thank Drs Chipev, Tsanev and Gratzer for critical scrutiny of the manuscript.

Electrified black holes

E. R. Harrison

National Radio Astronomy Observatory, Green Bank, West Virginia, 22901

Black holes with accretion disks are self-excited dynamos that generate large electric and magnetic fields. Along the spin axis they emit oppositely-directed narrow beams of high energy positrons and photons. The beams emanating from superholes are sufficiently powerful to explain extragalactic radio sources.

A BLACK hole has mass M , angular momentum J , and electrical charge Q , satisfying the relation

$$G^2 M^4 \geq J^2 c^2 - GM^2 Q^2 \quad (1)$$

where G is the gravitational constant and c is the speed of light. The equality sign denotes the maximum angular momentum and charge of the extreme Kerr-Newman metric. A spinning charged black hole has a magnetic dipole moment¹

$$\mathcal{M} = JQ/Mc \quad (2)$$

and at distances large compared with the gravitational length $R = GM/c^2$ the magnetic intensity obeys the familiar r^{-3} law. Normally, a large electric charge in a black hole would be rapidly neutralised by inflow of oppositely charged particles, and it has seemed reasonable therefore to suppose that charged black holes are not of great astrophysical importance. I shall attempt to show that a significant charge can in fact accumulate in black holes in quite general conditions, and that black-hole

electrodynamics may supply the long-sought-for explanation of the extended² and compact radio sources³.

Maximum electric charge

The maximum magnitudes of electromagnetic quantities, attainable in principle but not necessarily in practice, are denoted with a dagger. Thus a charge that contributes substantially to the mass of a black hole is approximately $Q_+ = G^{1/2} M$, and hence

$$Q_+/M \sim 10^{-18} e/m_p \quad (3)$$

where e/m_p is the charge-to-mass ratio of the proton. The corresponding electric potential is

$$\phi_+ \sim c^2/G^{1/2} \sim 10^{27} \text{ V} \quad (4)$$

and the electric field in the vicinity of a black hole is

$$E_+ \sim c^4/G^{3/2} \sim 10^{22} (M_\odot/M) \text{ V cm}^{-1} \quad (5)$$

(For $E_+ > 10^{16} \text{ V cm}^{-1}$, or $M < 10^6 M_\odot$, this field will break down spontaneously by the pair production of electrons.) The angular momentum that also contributes substantially to the mass is approximately $J_+ = GM^2/c$ and so the magnetic dipole moment is $G^{3/2} M^2/c$. In this case, the magnetic field intensity in the vicinity of the black hole is therefore

$$B_+ = E_+ \sim 10^{20} (M_\odot/M) \text{ G} \quad (6)$$

It is thus evident that black holes, in principle, can have the most intense macroscopic electromagnetic fields realisable in nature.

Gravity-induced electric charge

Eddington* (see also refs 5 and 6) showed that stars are positively charged, and that electric fields play an essential role in their internal structure. Within a star—such as the Sun—proton and electron gases contribute equally to the pressure gradient, whereas gravity acts mainly on the relatively massive protons; an electric field therefore mediates between the proton and electron gases. In effect, electrons have velocities greatly exceeding the escape velocity, and some therefore escape leaving the star positively charged with an internal electric field that retains the remaining electrons.

Let ψ and ϕ be the gravitational and electric potentials. In a star like the Sun the forces acting on a proton and an electron are approximately equal

$$-m_p \nabla \psi - e \nabla \phi = -m \nabla \psi + e \nabla \phi$$

and hence, neglecting the electron mass, m , the electric field is

$$-\nabla \phi = \alpha (m_p/e) \nabla \psi \quad (7)$$

where $\alpha = 0.5$. In more massive stars α approaches unity owing to the pressure of radiation acting on the electrons. From the divergence of equation (7) it follows that the charge to mass ratio of a star is

$$Q_*/M = G\alpha m_p/e \sim 10^{-36} e/m_p \quad (8)$$

where the gravity-induced positive charge Q_* is ~ 100 C/solar mass. The potential difference between the surface and centre of the Sun is $\sim 1,000$ V.

All self-gravitating systems containing free electrons have gravity induced positive charges of the order indicated by equation (8). The induced charge cannot be neutralised by the accretion of electrons nor can it be neutralised by surrounding a star with a negatively charged sheath. This is because the gravitational and electric fields exert everywhere a total force that acts equally on electrons and protons, and consequently an external ionised medium remains unpolarised. When Q is less (more) than Q_* , the external medium is polarised and there is an outflow (inflow) of electrons until Q_* is restored and the external medium is depolarised.

Black holes that form by stellar collapse have initial charge to mass ratios of the order given by equation (8) and

$$Q_*/Q_+ \sim (Gm_p^2/e^2)^{1/2} \sim 10^{-18} \quad (9)$$

Their electric potential $\phi_* \sim Q_* c^2/GM$ is

$$\phi_* \sim m_p c^2/e \sim 10^9 \text{ V} \quad (10)$$

and is independent of mass. With angular momentum J_+ the magnetic field intensity is

$$B_* \sim 10^{-18} B_+ \quad (11)$$

or $\sim 10^3$ G in the vicinity of the black hole.

Superholes

Almost all matter in the Universe has too much angular momentum, either initially to form into black holes or subsequently to be accreted by black holes. Angular momentum must therefore be removed and, in the case of accretion, a viscous accretion disk develops in which gas spirals in toward the black hole and angular momentum is transported away⁷⁻¹⁰. A weakly charged black hole thus has angular momentum $J_+ \simeq GM/c$ and approaches the extreme Kerr metric¹¹. An accretion disk generally lies in the rotational equatorial plane, and its orbital angular velocity has the same direction as the spin angular

Fig. 1 A black hole with an accretion disk acts as a self-excited dynamo. The black hole rotates, it has an initial gravity-induced positive charge, and it generates a dipole magnetic field. The magnetic field induces a positive charge in the disk, and the charge accreted is therefore proportional to the charge already in the black hole. The charge in the black hole thus grows exponentially while its mass grows linearly with time. The production of high energy positron beams, that emanate from the polar regions, is discussed in the text.

velocity of the black hole. Black holes that form in matter-rich galactic nuclei accrete gas (also tidally disrupted stars) and become supermassive^{12,13}, attaining masses $\sim 10^8 M_\odot$ on a time scale $\sim 10^8$ yr. These supermassive objects are conceivably the primary sources of energy in quasars and in violent nuclear activity¹⁴.

A system consisting of a charged spinning black hole encircled by an electrically conducting accretion disk contains the basic elements of a self-excited homopolar generator. Such systems, if they actually exist, constitute the most powerful electrical machines in nature.

It is emphasised that throughout this treatment general relativistic subtleties are ignored, and all results are therefore only rude order-of-magnitude estimates.

Black-hole homopolar generator

A rotating accretion disk (see Fig. 1) of high electrical conductivity has an induced electric field

$$\mathbf{E} = -\mathbf{v} \times \mathbf{B}/c \quad (12)$$

where \mathbf{v} is the orbital velocity and \mathbf{B} is the axisymmetric magnetic field of the black hole.

The potential difference between the inner and outer regions of a disk in Keplerian differential rotation is

$$\phi \sim Qc^2/GM \quad (13)$$

and is of the same order as the Coulomb potential of the black hole. From the divergence of equation (12) the volume charge density in the disk is

$$\sigma = (\mathbf{v} \cdot \nabla \times \mathbf{B} - \mathbf{B} \cdot \nabla \times \mathbf{v})/4\pi c \quad (14)$$

Electromagnetic models in which trapped magnetic flux is accreted are considered elsewhere (R. V. E. Lovelace, unpublished; R. O. Blandford and R. L. Znajek, unpublished). The dragging inward of magnetic flux is ignored in this discussion and hence $\nabla \times \mathbf{B} \sim 0$. It follows, using cylindrical coordinates (r, ϕ, z) , that

$$\sigma = -(B_z/4\pi c) \partial(rv)/r \partial r \quad (15)$$

Since $v \propto r^{-1/2}$, and \mathbf{B} in the disk is antiparallel to $\nabla \times \mathbf{v}$ for a positively charged black hole, the charge density is therefore also positive.

The basic mechanism of the proposed generator is that positively charged matter is accreted by a positively charged black hole. The induced charge σ in the disk is proportional to the charge Q in the black hole and therefore Q grows faster than the mass M . (The surface charge on the disk is determined by boundary conditions, and is not accreted.)

Let \dot{M} be the rate that mass is accreted, and \dot{Q} the rate that charge is accreted; further, let ρ_R and σ_R be the mass and charge densities of the innermost stable region of the disk close to the event horizon; then

$$\dot{Q}/\sigma_R \sim \dot{M}/\rho_R \quad (16)$$

where

$$\sigma_R \sim Q(GM)^{3/2}/8\pi c^3 R^{7/2} \sim Qc^6/8\pi G^3 M^3 \quad (17)$$

from equation (15). The mass density ρ_R is proportional to M/R^2c , and therefore

$$\dot{M}/\rho_R \sim G^2 M^2/\mu c^3 \quad (18)$$

where μ is plausibly ~ 10 . Equation (16), with equations (17) and (18), now becomes

$$\dot{Q} \sim Qc^3/8\pi GM\mu \quad (19)$$

and according to this simplified treatment the black hole charge grows exponentially on a time scale

$$T \sim 8\pi GM\mu/c^3 \sim 10^{-3}(M/M_\odot) \text{ s} \quad (20)$$

The initial 'seed' charge is the gravity induced value Q_* , and hence

$$Q \sim Q_* \exp(t/T)$$

Radiative discharge

In many respects, electrified black holes are different from pulsars. The spin and magnetic dipole axes of a black hole are coincident, whereas pulsars are oblique dipole rotators¹⁵. Pulsars have magnetospheres maintained by particle emission from the surface of a neutron star, and currents intersecting the surface enforce the magnetosphere into corotation¹⁶. The event horizon of a black hole cannot emit particles (quantum mechanical emission¹⁷ is negligibly small for the masses considered) and is not intersected by closed current loops. A black hole, therefore, is not embedded in a pulsar-like magnetosphere, and the huge potentials generated are therefore not easily short-circuited.

Electrons are attracted and accelerate along magnetic field lines that converge on the polar regions of the black hole. Let r_D be the outer radius of the disk; then the field lines not intersecting the disk converge on the polar regions at angles

$$\theta \lesssim (R/r_D)^2 \quad (21)$$

to the spin axis. The Larmor orbit radii of infalling electrons are small compared with R , and for R/r_D in the range 10^{-2} to 10^{-3} the electrons are confined to field lines of $\theta \leq 2^\circ$ – 6° . (The accreted electrons streaming down these narrow cones, in spite of space-charge limitation, may prevent the black hole from attaining large electrical potentials. Preliminary estimates indicate that this is unlikely.)

When the potential of the black hole is large, the infalling electrons emit curvature radiation that initiates a pair-production discharge^{18–20}. The created electrons and positrons of energy γmc^2 also emit curvature radiation consisting of photons of energy $\sim \gamma^3 \hbar c/R_c$, where R_c is the radius of curvature of the magnetic field lines. These photons cut across field lines and produce further electron pairs. All electrons plunge into the black hole and the positrons accelerate away in a narrow beam. If the photon mean free path, λ , for pair production is greater than a scale height $\sim R$ there is no significant discharge and the potential continues to rise. When $\lambda < R$, however,

pair-production avalanches until the black hole is discharged to the point where $\lambda \sim R$. With $\lambda \sim R \sim R_c$, the steady-state potential is found to be

$$\phi_s \sim 3 \times 10^{10} (mc^2/e)(M/M_\odot)^{1/2} \quad (22)$$

from formulae used in pulsar theory (refs 19, 20 and I. Lerche, unpublished). Thus a black hole of $10^8 M_\odot$ attains a potential 10^{20} V. The rate of converting gravitational energy into high energy particles is $\sim Q\dot{Q}c^2/GM$, or $\sim \phi^2 c/8\pi\mu$ from equation (19), and according to equation (22) the energy output in the beams is

$$L \sim 10^{37} (M/M_\odot) \text{ erg s}^{-1} \quad (23)$$

Accreting black holes emit low energy photons, and an alternative cascade mechanism is therefore possible (R. O. Blandford and M. J. Rees, unpublished). An infalling electron of energy γmc^2 inverse-Compton scatters a low energy photon to energy $\sim \gamma^2 kT$, where T is the temperature of ambient blackbody radiation²¹. The high energy photon now pair produces through photon-photon interactions, and the process avalanches if the photon mean free path, λ , is less than a characteristic distance $\sim R$. When $\gamma \lesssim mc^2/kT$, then $\lambda \sim (n\sigma_T)^{-1}$, where n is the blackbody photon density and σ_T is the Thomson cross section. In this case the vacuum breaks down at $\phi \sim 10^{12} T_4/T$ V when

$$M/M_\odot \lesssim 10^8 T/T_4 \quad (24)$$

and $T_4 \equiv 10^4$ K. Thus $10^8 M_\odot$ may be a limiting mass for the production of high energy beams. This type of breakdown, however, is not self-regulating; for if $\gamma > mc^2/kT$, then $\lambda \propto \gamma$, and the discharge quenches until the potential rises to the point where curvature radiation breakdown occurs in which $\lambda \propto \gamma^{-3}$.

Radio sources

Strong radio sources^{2,3} have energy outputs typically in the range 10^{42} – 10^{45} erg s⁻¹; a conspicuous characteristic feature is their double structure consisting of lobes of radio brightness extending in opposite directions from a quasar to an optically bright galactic nucleus; the extended double sources have estimated separations 10^5 – 10^7 light yr, whereas compact double sources have separations 10 – 10^2 light yr; also extended and compact sources often share the same optically bright central region, as in Cygnus A, and the radio brightness centres of extended and compact regions tend to be colinear. Various authors^{22–25} have advocated 'twin-beam' models for explaining double radio sources and shown that such models, in which oppositely directed beams of waves and relativistic particles created by quasars and galactic nuclei and lasting for 10^8 – 10^9 yr, have many attractive features.

The possibility that black holes have oppositely directed narrow beams of high energy particles is therefore of immediate interest in the study of radio sources. If it is granted that supermassive black holes with accretion disks exist, then we are provided with a natural mechanism that is capable of producing beams of sufficient power to excite radio sources. Positron-photon beams with entrained electrons will travel to great distances and energise the external magnetised medium. Thus, according to equations (22) and (23), superholes of mass $10^8 M_\odot$ emit high energy beams ($\gamma \sim 10^{14}$) with a power output of $\sim 10^{45}$ erg s⁻¹.

The specific properties of radio sources that can be explained by beamed emanations from electrified superholes are:

(1) Double structure: the two-component basic structure, often possessing remarkable symmetry, is the result of identical and oppositely directed narrow beams. Asymmetries and 'U' shapes (as in the 'head-tail' sources NGC 1265 and 3C 129 in rich clusters) are plausibly the result of density variations and relative motions of the intergalactic medium.

(2) Directional memory: Cygnus A and 3C 236 have compact double components aligned in the same direction as their extended double components, and the directional memory in these and other sources is provided by the spin axis of the

electrified superhole. Slow precession of the spin axis on a time scale of millions of years, owing to dynamic interaction with mass distributed in the nucleus, may explain the 'S'-shaped sources.

(3) Brightness distribution: the high energy beams progressively become more intense as the superhole grows in mass. So, in accord with observations²⁶, less luminous (therefore younger) sources have bright inner regions excited by greater beam intensity, whereas more luminous (older) sources have bright outer regions excited by beams that have attained great intensity over long periods of time.

Detailed investigations of electrified black holes will undoubtedly disclose more complex behaviours, such as, for example, non-quiescent discharges and beam pulsations on time scales $\sim GM/c^3$ of minutes to hours. These rapid fluctuations would be smoothed out in the extended radio brightness regions, but if 'core-halo' sources are two-component sources seen end on, the fluctuations might be detectable in the radio emission from the central milli-arcsecond structure of the core.

I am indebted to D. S. De Young, R. O. Blandford, M. J. Rees, and E. Tademaru for helpful comments and to the Astronomy Department, University of Virginia, for hospitality. NRAO is operated by Associated Universities Inc. under contract with the NSF.

letters to nature

Search for parity non-conserving optical rotation in atomic bismuth

THE Weinberg-Salam^{1,2} theory of the electromagnetic and weak interactions has been successful in predicting the neutral current interactions observed in neutrino experiments. An important further test for the theory is the experimental observation of predicted³ parity non-conservation in atoms. We are carrying out two related though distinct experiments to search for parity non-conserving optical rotation in atomic bismuth close to the allowed M_1 transitions from the ground state, $\lambda = 648$ nm (at Oxford) and $\lambda = 876$ nm (at Washington). Although our experiments are continuing we feel that there is sufficient interest to justify an interim report.

The predicted optical rotation angle close to the M_1 transition $i \rightarrow f$ is given by

$$\phi_p = \frac{-4\pi(n-1)LR}{\lambda}$$

where n is the refractive index and λ is the wavelength.

$$R = \frac{\text{Im}\langle f|E_1|i\rangle}{\langle f|M_1|i\rangle}$$

is the ratio of the parity non-conserving E_1 matrix element to the normal M_1 one. ϕ_p therefore has a dispersive dependence on frequency close to resonance. At resonance there is, of course, also absorption which limits the useful optical depth, $(n-1)L$, which can be used. For one absorption length at line centre the optical rotation at the dispersion peaks is $\pm R/2$.

A number of relativistic central field calculations of R have been made⁴⁻⁷ using both semi-empirical and Hartree-Fock methods. The ± 25 per cent agreement in the results is very satisfactory considering the differing starting points. We take

as average central field values $R_{876\text{ nm}} = -3 \times 10$, $R_{648\text{ nm}} = -4 \times 10^{-7}$, for a Weinberg angle $^{1,2} \sin^2 \theta = 0.35$.

The basic method used in the two experiments is the same: a brief description of the Washington experiment appeared recently⁸. In each experiment laser light at a frequency close to the M_1 transition is passed through two crossed polarisers between which is the bismuth oven ($T \simeq 1,500$ K). The transmitted light intensity has the form

$$I = A(\phi_p + \phi_M + \phi_R)^2 + B$$

where A and B are constants, ϕ_p is the optical rotation angle defined above, ϕ_M is an additional modulated angle produced by a Faraday cell and ϕ_R is any residual angle caused, for example, by misalignment of the polarisers. The basic signal, I_M , is that part of I which reverses with ϕ_M , normalised against changes in laser intensity and bismuth transmission. It is proportional to $\phi_M(\phi_p + \phi_R)$. The contributions from ϕ_p and ϕ_R are distinguished by the dispersive form of the rapid frequency variation of ϕ_p close to resonance.

There are a number of important differences between the experiments: (1) the pulsed parametric laser required at 876 nm has a linewidth too large to allow resolution of the individual hyperfine components which are separately observed in the 648-nm experiment. (2) The 648-nm line is overlaid by a molecular spectrum which limits the usable optical density to about 1 atomic absorption length. This difficulty is absent at 876 nm where an appreciably higher optical path length can be used. (3) Because the linewidth is much narrower in the Oxford experiment, the Faraday rotation in the bismuth caused by background magnetic fields is larger. To avoid the difficulty the oven is magnetically shielded and the experiment is designed to discriminate against bismuth Faraday rotations. (4) Largely because of the differences (1) to (3), different procedures have been adopted for picking out the sharp frequency dependence of the ϕ_p dispersion curve. In the Washington experiment this is achieved by repeatedly sweeping

the laser frequency through the resonance region while the signal I_M is accumulated in a multichannel analyser. The result can be fitted to the appropriate dispersion shape for several bismuth optical path lengths to subtract out the ϕ_R background. In the Oxford experiment the laser frequency is switched between two points of equal bismuth Faraday rotation, but opposite optical rotation. A small residual frequency dependent component of ϕ_R is subtracted out by repeating the experiment with a reduced bismuth optical path length.

Our results are as follows:

$$\text{Washington: } R_{876 \text{ nm}} = -8 \pm 3 \times 10^{-8}$$

$$\text{Oxford: } R_{648 \text{ nm}} = +10 \pm 8 \times 10^{-8}$$

where the quoted statistical error represents 2 s.d. There are, however, also systematic effects which we believe do not exceed $\pm 10 \times 10^{-8}$, but which are not yet fully understood. Within this systematic uncertainty the above results are each consistent with $R = 0$.

We conclude from the two experiments that the optical rotation in bismuth, if it exists, is smaller than the values -3×10^{-7} and -4×10^{-7} predicted by the Weinberg-Salam model plus the atomic central field approximation. Indeed Khriplovich⁷ has argued that the approximate theory used does overestimate R by a factor of ~ 1.5 . Lack of experience of this type of calculation means that more theoretical work is required before we can say whether or not the neglected many-body effects in the atomic calculation would make R consistent with the present experimental limits.

General relativistic incompressibility

SIXTY years ago, Schwarzschild¹ developed what he, and others through the years, regarded as the general relativistic solution for a static, spherically symmetric, incompressible fluid sphere with equation of state $\rho = \rho_0 = \text{constant}$. Others have rejected the incompressibility interpretation of this solution including Eddington² who regarded $\rho - 3p = \text{constant}$ as the incompressible equation of state. We present here a new definition of incompressibility, consistent with basic principles of relativity. We then consider the natural generalisation of the Schwarzschild equation of state to general relativity, namely the constancy of proper density, and find that this approximates a truly incompressible fluid more closely than that presented by both Schwarzschild and Eddington. This could have interesting consequences in astrophysics since the maximum value of gravitational redshift, as well as the upper limit to the mass of a

neutron star, are larger for this model than for the Schwarzschild model, which is traditionally considered.

For the Schwarzschild solution, the upper limit for $2m/r_0$ is 0.889 because at this value the pressure becomes infinite at $r = 0$ (r is the Schwarzschild radial coordinate, m is the total energy of the body, $r = r_0$ at its surface and $G = c = 1$). Thus, for this case, the ultimate limit for static bodies, $2m/r_0 = 1$ cannot be approached. It has also been shown³ that under the seemingly natural restriction for normal bodies, $dp/dr \leq 0$, the maximum value for $2m/r_0$ which can be attained, irrespective of the equation of state, is 0.889, that is, in the Schwarzschild body. Moreover, this value corresponds to a maximum gravitational redshift of $z = 2$, and for some time, when the redshifts of quasi-stellar objects were piling up to $z = 1.95$, the situation was tantalising indeed. Since then, however, the z values of quasi-stellar objects have easily broken the $z = 2$ barrier. Also, ultradense matter raises the controversial question regarding the speed of sound exceeding the speed of light⁴⁻⁶.

In recent years, there has developed a growing realisation that $\rho = \text{constant}$ does not represent a constancy of physical energy density because of the role of gravitational binding energy⁷— ρ represents total energy density excluding gravitational energy.

True incompressibility, an idealisation in the realm of classical physics, is an even more remote concept in general relativity, because its realisation is already precluded in special relativity. Complete rigidity implies the instantaneous velocity of propagation of interactions. Instead, we propose the following definition of incompressibility.

A static, spherically symmetric body is incompressible if its equation of state is such that the pressure becomes infinite at $r = 0$ precisely when the limit $2m/r_0 = 1$ is reached.

Surely this represents the ultimate stiffness of matter which can be envisaged, and it can be envisaged only as a limit; it cannot be attained⁸, which is all to the good.

For physically reasonable equations of state, how close can matter come to being incompressible? We will consider this question in conjunction with our definition: how close can a static body come to having $2m/r_0 = 1$?

We first consider Eddington incompressibility. Letting $\rho - 3p = B = \text{constant}$, we readily solve for one component of the metric

$$ds^2 = e^{\nu} dt^2 - e^{\lambda} dr^2 - r^2 (d\theta^2 + \sin^2\theta d\phi^2)$$

in terms of pressure. From the Einstein field equations

$$p' = -\frac{\nu'}{2}(B + 4p); \quad p = \frac{Ke^{-2\nu} - B}{4}$$

where the prime $\equiv d/dr$ and K is the constant of integration.

Unfortunately, we then learn that the coupling of the equations for density and pressure which is demanded by the Eddington equation of state, leads to far more difficult differential equations for ν and λ themselves. The equation for ν is

$$CKe^{-2\nu} \left(\nu'' - (\nu')^2 - \frac{6\nu'}{r} - \frac{6}{r^2} \right) + CB \left(-\nu'' - (\nu')^2 + \frac{2}{r^2} \right) - \frac{4\nu'^2}{r^2} - \frac{4\nu''}{r^2} - \frac{8\nu'}{r^2} = 0; \quad C = -8\pi G$$

This is to be compared to the Schwarzschild equation of state $p = p_0$ which yields

$$C\rho_0 r^2 = (e^{-\lambda} r)' - 1; \quad e^{-\lambda} = 1 + \frac{C\rho_0 r^2}{3};$$

$$rDe^{-\nu/2} = e^{-\lambda} \nu' - (e^{-\lambda})'$$

With $e^{-\lambda}$ known, this easily leads to the solution for ν .

Nevertheless, we now have computers which were unavailable to Eddington. The numerical solutions have revealed that, at every stage, the Eddington equation of state corresponds to a body which is less stiff than the Schwarzschild body of equal mass and radius. This is consistent with Buchdahl's proof³ because

$$\frac{dp}{dr} = 3 \frac{dp}{dr} < 0$$

We feel that both the Schwarzschild and Eddington equations of state suffer from the deficiency of being too closely wedded to classical concepts. Relativistically, all energy, including gravitational energy, contributes to the total mass of a body, and in the extremely strong gravitational fields here considered, where bodies are close to their gravitational radii, gravitational energy is very significant indeed. In this respect, we now consider the natural general relativistic generalisation of the Schwarzschild equation of states.

The total relativistic mass of a body can be expressed as

$$M = \int_0^{r_0} \rho(r) 4\pi r^2 dr$$

This is found by matching to the exterior Schwarzschild metric. Since the integration is not over proper physical volume, clearly $\rho(r)$ does not represent proper energy density. If, however, we write

$$M = \int_0^{r_0} \frac{\rho(r)}{\sqrt{g_{rr}}} 4\pi r^2 \sqrt{g_{rr}} dr$$

we recognise $\rho_{\text{proper}} = \rho(r)/\sqrt{g_{rr}}$. In fact, in the limit of weak fields, it is readily shown that this modification accounts for gravitational binding energy⁷.

Thus, to generalise the Schwarzschild equation of state

$$\rho_{\text{proper}} = \frac{\rho(r)}{\sqrt{g_{rr}}} = \text{constant}$$

or

$$\rho(r) = A e^{\lambda/2}; A = \text{constant}$$

In conjunction with the Einstein field equations, this yields

$$CAe^{\lambda/2} = e^{-\lambda} \left(\frac{1}{r^2} - \frac{\lambda'}{r} \right) - \frac{1}{r^2}$$

$$Cp = \frac{1}{r^2} - e^{-\lambda} \left(\frac{1}{r^2} - \frac{v'}{r} \right)$$

$$Cp = e^{-\lambda} \left[\frac{v'\lambda'}{4} - \frac{(v')^2}{4} - \left(\frac{v'}{2r} - \frac{\lambda'}{2} \right) - \frac{v''}{2} \right]$$

These equations were solved by numerical integration. The program was verified by solving the Schwarzschild equations, which led to results in agreement with the analytical solution to five significant figures. The results of the computer analysis of the equations are shown below. The equations were integrated outwards with infinite central pressure, and the radius of the body was determined by the condition that the pressure vanishes at the surface.

The graph compares pressure with e^{λ} rather than with radius because

$$(e^{\lambda})_{\text{surface}} = \left(1 - \frac{2m}{r_0} \right)^{-1}$$

Fig. 1 Comparison of the behaviour of the constant $-\rho_{\text{proper}}$ solution (—) with that of the Schwarzschild solution (---).

yields $2m/r_0$ directly, obviating the necessity of integrating to find the total mass of the system. The Eddington solution has not been analysed for infinite central pressure. From our previous discussion, however, the Eddington equation of state corresponds to matter which is less stiff than that of Schwarzschild. From Fig. 1 $(e^{\lambda})_{\text{surface}} = 12.1$ for ρ_{proper} constant, corresponding to the value $2m/r_0 = 0.917$. Thus, by our criterion, we have material which is stiffer than in Schwarzschild's and Eddington's work. Moreover, it implies a larger maximum gravitational redshift ($z = 2.48$) of spectral lines from the surface of a star. Although it represents an improvement over the Schwarzschild limit, redshifts have been observed to exceed this value⁸ and hence this alone would not suffice to provide an alternative hypothesis to the cosmological interpretation of QSOs.

Eddington's condition is equivalent to the classical concept of incompressibility because classically, for a homogeneous substance, mass and particle density are proportional. The Schwarzschild condition is a generalisation of this concept to special relativity since it takes into account changes in mass from motion, and the $\rho_{\text{proper}} = \text{constant}$ condition, incorporating gravitational energy as well, is a further generalisation of this same concept. It is not surprising, therefore, that among the three, the Schwarzschild fluid should be stiffer than that of Eddington, and the constant $-\rho_{\text{proper}}$ fluid stiffest of all.

As a final note, it is worth mentioning that Bondi⁹ went further still, achieving $2m/r_0 = 0.970$ under the assumptions $\rho > 0, p > 0$. His solution, corresponding to a "thin shell of matter containing a space stuffed full with density-free pressure", is, however, entirely unphysical.

We are grateful to Dr S. Wong and Mr D. McGregor for computer assistance.

Is the velocity of P_n an indicator of Q_a ?

IN a recent paper Booth *et al.*¹ showed that short period teleseismic P waves are recorded with relatively small amplitudes at long range seismic measurement (LRSM) stations in the western United States compared with those in the eastern half of the country. This is in agreement with the results of Jordan *et al.*² and several more recent studies. Booth concluded that this might be because the upper mantle anelastic quality factor Q_a is higher in the east, and consequently waves passing through it suffer less absorption.

The hypothesis has important consequences for the measurement of magnitude (m_b) and the proposal made by the United States and the Soviet Union to limit the size of their nuclear weapon tests stimulated further investigations of the idea. There is not an obvious way of doing so because opportunities to make reciprocal station-source experiments (firing at one station and recording at another, then firing at the second and recording at the first) are few. Would other geophysical quantities provide an indicator of Q_a in the upper mantle?

The velocity of the Moho refracted wave, P_n , is an obvious candidate; Herrin and Taggart³ have proposed that the variation in velocity of P_n might be due to fundamental differences between east and west in the upper mantle of North America. Evernden⁴ used P_n velocities to improve the estimates of magnitudes of near and near-regional earthquakes, and Alsop⁵ estimates Q_a in the uppermost mantle of the United States with the help of P_n waves.

The result of plotting Herrin and Taggart's observations³ of P_n velocity against the average short period P-wave amplitude residuals for stations overlying a particular P_n velocity is illustrated in Fig. 1. The two horizontal lines are simple averages. Cleary's⁶ data from the homogeneous (LRSM) network of stations are included with those of Booth *et al.* All five observations at 8.15 km s^{-1} are in Wisconsin and Minnesota where according to Herrin and Taggart, the P_n velocity is not well determined. (Note, however, that Smith *et al.*⁷ give a P_n velocity of 8.07 km s^{-1} for this area and that this eliminates the anomalous value.)

The correlation illustrated in Fig. 1 establishes an empirical relationship between the velocity of P_n and amplitude residuals

in North America. As it seems reasonable to suppose that the amplitude variations are caused by Q_a variation, we conclude that Q_a and the velocity of P_n are correlated. Archambeau *et al.*⁹ have already implied a relation between upper mantle P velocities and Q_a . The work which is developing from these key observations reported in this note indicates that such a relationship does exist, and that useful estimates of effective Q_a of the upper mantle and of amplitude (magnitude) residuals can be made wherever there are reliable measurements of P_n velocity. Since P_n velocities are available from most parts of the world it is possible to improve the accuracy of estimates of seismic yields of underground explosions. The more fundamental investigations into the physical significance of the observations are being pursued.

Use of phototransfer for the anomalous fading of thermoluminescence

THE occurrence of anomalous fading of thermoluminescence (TL) in minerals typical of the inclusions found in archaeological pottery has been reported¹. This effect leads to an erroneous evaluation of the archaeological age using conventional TL methods. Consequently it introduces serious problems in the dating of such materials. Here the phototransfer technique (re-excited glow)² was applied. The results indicate that in some materials anomalous fading may be circumvented, or at least substantially reduced. Of the materials of interest in TL dating that display anomalous fading (zircon, fluorapatite and plagioclase feldspars labradorite, andesine and bytownite), fluorapatite and zircon³ were found to be the most promising for the application of the phototransfer technique.

The samples tested (from the same specimen as used by ref. 1) were in the form of loose, crushed, grains and their TL was observed with apparatus that has been described by Aitken and Fleming⁴. Before the experiments these materials were annealed for 15 min at 700°C in an atmosphere of oxygen-free nitrogen. Ultraviolet illumination (usually 1-min exposure) of the samples was made at room temperature (RT) by means of a 300-W xenon lamp, the light from which was passed through a f/4.0 grating monochromator. A $^{90}\text{Sr}/^{90}\text{Y}$ β source was used for the irradiations.

The phototransferred TL (PTTL) was observed using the following procedure: first, irradiation at RT and subsequently erase TL to 500°C ; second, illumination with monochromatic light at RT and third the observation of re-excited TL by means of a glow curve of 500°C . The re-excited glow curves arising from phototransfer, obtained for fluorapatite and zircon are shown in Fig. 1. They are compared with the glow curves obtained after a short β

Fig. 1 Relationship between average station amplitude residuals and P_n velocity. Horizontal bars are obtained by summing all individual station amplitude residuals values $> 8.1 \text{ km s}^{-1}$ and all $< 8.0 \text{ km s}^{-1}$ and dividing by n the total number of observations in each velocity range.

Fig. 1 TL glow curves: (a), zircon and (b) fluorapatite. In both *a* and *b*, — — — represents a typical PTTL glow curve, — — — β -induced TL.

irradiation. In the case of zircon, the re-excited glow curve after ultraviolet illumination is different from that obtained after β irradiation; a peak is observed at 135°C which is close to the dominant peak at 125°C that is induced by β rays.

From the observations of PTTL following drainage to different maximum temperatures, donor levels (populated traps) have associated TL peaks in the region 500–700°C in the case of fluorapatite and in the region 620–700°C for zircon. We tested these donor levels for anomalous fading—samples of zircon and fluorapatite were given a dose of irradiation of ~ 25 krad and stored together with unirradiated samples for periods up to six months. The transferred TL from the irradiated samples was compared with the transferred TL obtained from the previously unirradiated samples that were β irradiated with the same dose just before measurement. Table 1 lists the results of the fading tests for the zircon and fluorapatite samples. In the case of zircon the donor levels associated with the 320-nm illumination were found not to fade and those levels associated with other wavelengths (280 and 240 nm) show some loss. Detailed investigation of the variation of transferred TL with wavelength of illumination³ indicates that there may be two types of centre involved in the transfer, and it appears that one of them does not fade.

Table 1 Long term fading test: % loss of PTTL (experimental error $\pm 3\%$)

Sample Illumination	Test period (months)	% loss transfer 320 nm	% loss transfer 280 nm	% loss transfer 240 nm
Zircon	6	0	15	20
Fluorapatite	3	3	No data	
	5	23		

The results for fluorapatite were less conclusive and the inconsistency (see Table 1) of 3% and 23% fading after 3 and 5 months storage respectively is to be investigated. As a comparison with conventional TL, tests for anomalous fading of the β induced glow curve ($< 500^\circ\text{C}$) were carried out. For storage after irradiation (in the dark, at RT) for periods of 1 h (zircon) and 0.5 h (fluorapatite), the glow curves showed $\sim 15\%$ fading in the high temperature region ($> 150^\circ\text{C}$) that is, where thermal untrapping had not occurred. Similar results were obtained with PTTL. The observations of the fading of the β -induced TL are in agreement with the findings of Wintle⁴, who has found that the anomalous fading of TL is not necessarily short lived; Fig. 2 shows results from her work for fluorapatite and zircon. These graphs indicate that, using conventional TL, extensive loss is to be expected for storage over a few months in the case of fluorapatite though less, but still serious, fading in the case of zircon.

Fig. 2 Anomalous fading of TL. % TL left at 270°C coordinate (fluorapatite (a)) and at 300°C coordinate (zircon (b)) against storage time, at 10°C (log/log plot).

For the purpose of dating, the growth in intensity of transferred TL with dose accrued by the sample (referred to as the 'growth characteristic') has also been investigated. Minerals such as zircon and apatites have high uranium and thorium content; typically 10^2 – 10^3 p.p.m. Consequently the effective internal radiation dose over archaeological time is² in the region of tens of kilorads. For zircon and fluorapatite it has been found that the growth characteristic is linear up to 20 krad of accrued dose (see Fig. 3) for 320-nm illumination. Other wavelengths have also been investigated³. The non-zero intercept on the equivalent dose transferred axis results from a residual ultraviolet response, which in the case of zircon is significant. (The 'residual ultraviolet' excited TL refers to the glow curve obtained after ultraviolet illumination where the sample had not been irradiated since annealing to 700°C.) Investigation of the wavelength dependence of PTTL and the residual ultraviolet excited TL indicates, however, that the situation should be improved for illumination with longer wavelengths. This and further work on the transfer properties of zircon and fluorapatite are to be reported elsewhere.

Fig. 3 Growth characteristics for (a) zircon and (b) fluorapatite under 320-nm (5 nm B-P) illumination. The 'equivalent dose transferred' (EDT) refers to the β dose required to be administered to the sample to produce a TL peak height that is equivalent to that of the PTTL peak. In the case of fluorapatite the 250 °C peak was used and for zircon the 125 °C β -induced peak was used to represent an EDT for the 135 °C ultraviolet-excited peak.

I thank Dr M. J. Aitken for supervision and Professor M. Schlesinger for his help. The samples were supplied by Dr F. B. Atkins. An equipment grant from the Nuffield Foundation is acknowledged.

Quantitative approach to molecular resolution electron microscopy

MANY attempts have been made to resolve individual atoms as ions, in molecules, and in crystals using conventional and scanning transmission electron microscopy^{1–5}. The results have been presented in the form of photographs for essentially qualitative assessment. In order to put the technique on a quantitative basis, we have analysed images of isolated molecules on thin supporting films using a digitising microdensitometer. We report here the results for a particular test molecule with a readily identified structure containing one heavy atom ($Z = 80$) for reference and two medium ones ($Z = 35$) for

determining the reliability threshold. As yet, images of lighter atoms ($Z = 16$) have been obtained only after extensive processing¹, which impedes quantitative assessment.

We used a JEM 100 C microscope (JEOL Ltd, Japan) with voltage 120 kV, tilted beam dark field operation, objective aperture for spatial periods down to 0.24 nm, negative defocusing close to the Scherzer condition, and calibrated magnification 830 k. We chose Kodirex film (Kodak-Pathé, France) for the recording, as it has appropriate sensitivity, modulation transfer function (MTF), and detective quantum efficiency (DQE) characteristics. The specimen consisted of Merbromin ($C_{20}H_{10}Br_2HgO_6$) (K & K: ICN Life Science Group, USA) molecules deposited from solution in water on the support film. Figure 1 shows the probable structure determined by modelling: the separations of the mercury and bromine atoms are about 1.1, 1.0 and 0.6 nm. The support was a 400-mesh copper grid coated with Formvar, a holey carbon film, and an ultrathin (≤ 1.5 nm) amorphous boron layer. We found that the boron layer was stronger and more uniform over the holes than carbon ones, and gave less background noise. Bromine atoms are usually sufficiently well resolved against uniform regions of the support film to present few problems. We deliberately chose a molecule close to a non-uniform region in order to demonstrate the danger of interpreting from 'improved' photographs, and to demonstrate that the quantitative analysis of the original recording yields a measure of its reliability. Figure 2 shows two enlargements made from the same part of the original. Fig. 2a was printed conventionally. (The process could not resolve the low contrast details visible in the negative.) Fig. 2b was obtained by copying with four times magnification on high gamma duplicating film and then printing on hard paper. It reveals the bromine atoms;

Fig. 1

but the granular structure and the lack of intermediate tones makes it difficult to distinguish the molecule from the noise. There are other processing methods, which yield cleaner pictures¹; but the probability of misinformation is greater.

In our quantitative approach, we first examined the original recording using a low magnification optical microscope with numerical aperture sufficiently large for the range of spatial periods. We then evaluated likely regions using a microdensitometer. This was a flat-bed model which

Fig. 2 Triad of mercury and bromine atoms in merbromin molecule; b has been processed for clarity.

Fig. 3

had been modified in the laboratory for scanning and digitisation. A $(25\text{-}\mu\text{m})^2$ sampling aperture yielded reasonably constant MTF for spatial periods down to $\sim 0.15\text{ mm}$, and that we found adequate for Kodirex. We chose the sampling step somewhat smaller than half the minimum spatial period for the microscope, $80\text{ }\mu\text{m}$ corresponding to 0.096 nm . The data were tabulated by computer. A crude contour map is shown in Fig. 3: each number indicates the highest of ten contour levels which passes within half a spacing of a grid point. (We found it necessary to use a second evaluation for the map with a larger sampling aperture so that the background fluctuations were reduced by MTF roll-off.) The data from single line scans through the atoms are shown in Fig. 4. We considered it inappropriate to fit curves through the points, as that was not particularly informative in view of the sampling process. We also found that the measured optical densities, D , were not very helpful, and we decided to refer the values to the mean \bar{D} (horizontal line) and the root mean square fluctuation \bar{D} for background scans on either side of the molecule. The resulting local signal-to-noise ratios $(D-\bar{D})/\bar{D}$ were 3.8 and 2.0, 1.8 for the mercury and bromine atoms. The mean Hg/Br signal ratio for several evaluations with different specimens was 1.9, suggesting reasonable prospects for heavy/light atom discrimination. The variance within the (admittedly) small sample was disconcerting, implying poorer reliability than we had supposed from the visual assessment.

Fig. 4

The scan profiles can be misleading: for example, the peaks to the right of the molecule may be interpreted as other atoms. Careful analysis of the patterns in two directions normally separates the useful information from the "noise"; but that clearly relies on previous knowledge of the structures. The widths of the profiles are no guide for the resolution attainable. We believe that the minimum workable separation is significantly smaller than twice the limiting spatial period; but, unfortunately, it is certainly larger than the atomic bond distances. (We are now trying molecules with smaller spacings.)

We are sufficiently encouraged by the results for uranium, mercury, barium, iodine, strontium⁵ and bromine atoms to continue the search downwards. In view of the background fluctuations, we are doubtful of the prospects for light atoms, but we remain hopeful for chlorine ($Z = 17$). In another direction, we are collaborating in an application to tag subunits of large biomolecules. We are also developing more practical techniques of image analysis using a minicomputer with a graphics display terminal.

Low temperature specific heat of glasses and amorphous solids

IN a previous paper¹ we attributed the anomalous low temperature thermal properties of amorphous materials to the inherent nature of the amorphous state, conceived of as the crystalline state saturated with the most favoured dislocations². Using Granato's vibrating string model³ of a dislocation, an estimate of the excess specific heat of $\text{Pd}_{0.775}\text{Cu}_{0.06}\text{Si}_{0.165}$ was provided. The purpose of the present note is to clarify several points in our earlier paper.

The experimental value^{4,5} of the specific heat of glassy $\text{Pd}_{0.776}\text{Cu}_{0.06}\text{Si}_{0.165}$ previously quoted is actually the electronic specific heat of the crystalline solid and not the linear contribution associated with the amorphous state. For the anomalous linear region of amorphous $\text{Pd}_{0.775}\text{Cu}_{0.06}\text{Si}_{0.165}$ the data of Golding, Bagley and Hsu¹ indicate an upper limit of $C_v/T \approx 1.1 \times 10^4 \text{ erg mol}^{-1} \text{ K}^{-2}$.

As the previous calculation for the linear specific heat of amorphous $\text{Pd}_{0.775}\text{Cu}_{0.06}\text{Si}_{0.165}$ used weighted averages for the parameters involved, it is felt that a revised calculation using experimentally determined values is in order. The pertinent values determined by Golding, Bagley and Hsu¹ are $\rho = 10.52 \text{ g cm}^{-3}$, $G = 3.48 \times 10^{11} \text{ dyne cm}^{-2}$, and $\theta = 252 \text{ K}$. Noting that the saturation condition corresponds to a dislocation density $\Lambda = (2r_c^2/3)^{-1}$ where r_c is the core radius, then saturation occurs for $\Lambda = 7.9 \times 10^{13} \text{ cm}^{-2}$ (a weighted average of $4.1 \times 10^{-8} \text{ cm}$ has been assumed for the lattice parameter). Substituting the above values into the expression for the dislocation contribution to the specific heat.

$$C_v = \frac{\rho \pi^2 \Lambda a^2 N k T}{3 z \theta} \quad (1)$$

now yields $C_v/T = 8.6 \times 10^4 \text{ erg mol}^{-1} \text{ K}^{-2}$, as compared with the experimental value of $1.1 \times 10^4 \text{ erg mol}^{-1} \text{ K}^{-2}$. It must be noted that this is an absolute upper limit on the calculated dislocation specific heat contribution.

Lu and Nelkin⁶ have also examined the low temperature thermal properties of glasses in terms of dislocations, indicating that a dislocation density of 10^{10} – 10^{11} cm^{-2} is required to

explain the linear specific heat (this calculation employed the Lifshitz-Kosevich⁷ model of an edge dislocation) and further speculating that the tunnelling of dislocation cores between equilibrium configurations may be responsible for the phonon scattering (a similar idea has been advanced by Anderson⁸ for a sessile dislocation in a complex lattice). Tunnelling of the cores would be consistent with the two-level systems postulated in the tunnelling states model^{9,10}.

There are difficulties associated with the concept of dislocations in glasses, the validity of the string model at these high densities, and the behaviour of the strain fields at this density. These are all questions which need to be addressed. But Ashby and Logan¹¹ have pointed out that within the framework of the random-network model "dislocation-like" features are possible in glasses and that they may have a very high density. In earlier work Scott and Giles¹² have succeeded in explaining the thermal conductivity of Teflon from 0.17 to 4.0 K on the basis of dislocation scattering of phonons. Further, small-angle X-ray scattering experiments are not inconsistent with the presence of dislocation strain fields in glasses⁶. Caution should also be exercised in strict application of the string model to explain both the specific heat and thermal conductivity of glasses. But in view of the rather interesting, although speculative, implications of these ideas, we feel that the concept of dislocations in amorphous solids is worthy of further examination, especially its compatibility with the tunnelling states model.

Fig. 1 View of venting St Augustine volcano as the aircraft lines up for a plume penetration.

1976), taken as the National Center for Atmospheric Research (NCAR) Electra aircraft (instrument boom visible to left) prepared to enter the plume on a sampling run, is shown in Fig. 1. During this and other sampling runs ice nuclei in the air were captured on Millipore membrane filters using the NCAR SAMOVAR Air Filtration System⁶.

To reduce the analytical uncertainty that seems to be associated with all methods of membrane ice nucleus analyses, rather than filtering aerosol through single 3.7- or 4.7-cm diameter filters as is commonly done, an array of filters was produced by first exposing a single 28.7-cm square, 0.45 μm pore diameter, Millipore filter supported by a fibre glass backing. This large filter was then sectioned with a circular stainless steel die to produce 25 separate 4.7-cm diameter filter disks all exposed in the same volume of air. Each of the segments is considered to be equivalent to each of the others. Between 0.5 and 5.0 m^3 of air flowed through each filter disk at a rate of 0.15 $\text{m}^3 \text{min}^{-1}$.

One part of the experiment consisted of exposing a large Millipore filter 800 km upwind of the volcano over the Gulf of Alaska in marine air far removed from volcanic and human influence. This air was considered to contain a representative background ice nucleus population for the air subsequently moving on to the coast of Alaska. The first exposure was followed by exposure of a new filter totally within the plume of the volcano on the following day. Other measurements included exposure of a filter in background air and re-exposure of the same filter within the plume. This sequence was followed to observe whether plume effluents deactivated natural ice nuclei. Yet another filter was exposed solely in plume air 16 d after the second major eruption.

The Millipore filter sections were processed in a thermal diffusion chamber identical to the one described by Langer and Rodgers⁷, except for the water vapour source for these studies which consisted of three thermally controlled ice-covered plates instead of ice cubes. From each large filter array, five filter disks were processed at -10 , -15 , and -20 $^{\circ}\text{C}$. To calibrate the system to operate at water saturation, or possibly slight supersaturation, the filter substrate and ice temperatures were adjusted so that a fog, and eventually droplets, appeared on aluminium foil placed in the processing chamber. Further evidence of proper vapour control was seen when water-depleted 'halos' formed around growing ice crystals on the filters being processed; thus it may be suggested that condensation-followed-by-freezing may have been occurring in addition to nucleation by deposition. Typical ice crystal counts per filter were 1–20 at -10 $^{\circ}\text{C}$, 9–90 at -15 $^{\circ}\text{C}$, and 200–800 at -20 $^{\circ}\text{C}$ before

Airborne ice nuclei near an active volcano

ACTIVE volcanoes have been suggested as being sources of atmospheric ice nuclei^{1,2}, the rare yet crucial particles that initiate much of the Earth's precipitation. Other studies indicate that some volcanoes are not adding ice nuclei to the atmosphere or may be deactivating natural ice nuclei^{3–5}. We report here measurements of atmospheric ice nucleus concentrations upwind and within the effluent plume of St Augustine, an actively venting island volcano situated at the base of the Aleutians in the mouth of Cook Inlet, Alaska ($59^{\circ}20' \text{N}$, $153^{\circ}30' \text{W}$). St Augustine erupted violently on January 23, 1976 and then again on February 4, 1976. We find no evidence for ice nuclei production by this volcano. Between and after the major eruptions the volcano actively vented giving off gaseous and particulate matter. Sulphur dioxide concentrations in the plume were $>5 \text{ p.p.m.}$ (J. Moyers, unpublished) and the total particulate loading was $\sim 100 \mu\text{g m}^{-3}$ (W. Zoller, unpublished) during the venting stages. A photograph of the venting volcano (February 1,

Fig. 2 Atmospheric ice-nucleus concentrations measured upwind and within the plume of erupting St Augustine volcano, Alaska. The solid dots represent the ice nucleus concentrations observed; the trend lines serve merely to bracket the separate ice nucleus concentration sets. *a*, Gulf of Alaska, January 31, 1976; *b*, plume, February 1, 1976; *c*, background and plume, February 1, 1976; *d*, plume, February 20, 1976.

subtraction of background counts (observed on unexposed filters) of 9, 6, and 45 crystals, respectively. The resultant crystal counts were corrected for volume effect⁸ and then normalised to a unit volume of air.

Results from analyses of four filter arrays are shown in Fig. 2 where it can be seen that the air over the Gulf of Alaska sampled on January 31, 1976 (*a*) contained more ice nuclei than did the volcanic plume sampled on the following day, February 1 (*b*). Comparisons between the ice nuclei in the plume air on February 1 (*b*) and the ice nuclei observed on filters exposed to background air followed by re-exposure to plume air (*c*) indicate that slightly higher ice nucleus concentrations were observed in the latter samples. The plume air of February 20 (*d*) contained ice nuclei in concentrations slightly in excess of the background air measured over the Gulf of Alaska (*a*).

All of the ice nucleus measurements shown in Fig. 2 fall within the range of 'typical' ice nucleus spectra observed in 'background' air at other locations around the globe⁹. The concentrations of ice nuclei active at -20°C in the plume on February 20 (*d*) (highest concentrations observed) fall between 560 and 920 nuclei m^{-3} . These values bracket the measurement of 0.7 nuclei l^{-1} active at -20°C measured in the plume of venting Mt Baker (Washington) during March and June 1975 as reported by Radke *et al.*¹⁰.

We suggest, on the basis of our measurements, that the effluent plume of St Augustine was not contributing significantly to background atmospheric ice nucleus concentrations on the days studied. There is some suggestion that the effluent gases may be deactivating natural ice nuclei in some cases as evidenced by relatively low ice nucleus concentrations measured on February 7. If this is so, this deactivation is relatively small compared with the inherent variability of natural atmospheric ice nucleus concentrations generally observed in the atmosphere¹¹. This variability could also explain these lower measurements. Since the particulate output of all the Earth's volcanoes (actively erupting and venting) is estimated to be ~ 0.005 of the total Earth-derived aerosol load¹¹, it is further suggested that

volcanoes venting similarly to St Augustine are probably exerting little influence on local atmospheric ice nucleus concentrations and negligible effects on global atmospheric ice nucleus concentrations. We anticipate measuring ice nucleus concentrations within the plume of an erupting volcano in the coming years.

We thank the NCAR Research Aviation Facility and the crew of the NCAR Electra for flying the sampling missions. Support was received from the NRC-NAS Research Associate Program and the Atmospheric Physics and Chemistry Laboratory of the NOAA.

Early Archaean age for the Sebakwian group at Selukwe, Rhodesia

WE present here the results of a Rb-Sr age and isotope study of granite (about 70% SiO_2) from the north-eastern sector of the Mont d'Or formation in the central part of the Rhodesian Archaean craton (Fig. 1). A nine-point Rb-Sr whole rock isochron (Fig. 2, Table 1) yields an age of $3,420 \pm 60$ Myr, with an initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of 0.711 ± 0.001 (both errors at 1σ). We regard this as the age of intrusion.

The current nomenclature for the subdivisions of Rhodesian greenstone belts invokes three informal lithostratigraphic 'groups', the Sebakwian, Bulawayan and Shamvaian.

Fig. 1 Geological sketch map of part of the Rhodesian Archaean craton, showing locality of Mont d'Or granite.

Fig. 2 Rb-Sr whole rock isochron plot for Mont d'Or granite samples. Errors are quoted at the 1 σ level. Error factor required to achieve perfect least squares fit is 2.5. Decay constant for ^{87}Rb is $1.39 \times 10^{-11} \text{ yr}^{-1}$.

The Sebakwian is the oldest, with the younger Bulawayan and Shamvaian groups together constituting the main greenstone belts¹. Age measurements on volcanic rocks from the Bulawayan group indicate an age of eruption of about 2,700 Myr (ref. 2). The Selukwe greenstone belt is assigned to the Sebakwian group on the latest (1971) edition of the geological map of Rhodesia issued by the Rhodesia Geological Survey. The Selukwe area is unique in that the succession is inverted and forms part of the lower limb of a large recumbent fold³⁻⁷. This structure is called the Selukwe nappe.

The Mont d'Or formation consists largely of quartzofeldspathic rocks containing chlorite and sericite. The sericitised nature of many of the rocks has led to dispute concerning the original nature of the formation. Stowe³⁻⁵ favours a largely sedimentary origin and regards the Mont d'Or formation as the lowest (oldest) stratigraphic unit in the nappe structure, but describes the presence of later, small, irregular intrusive bodies of granite. Cotterill⁷, on the other hand, considers that the greater part of the formation consists of a granite which is intrusive into the nappe structure. He recognises meta-sedimentary enclaves within the granite, but regards them as lateral equivalents of the Wanderer formation, the major sedimentary unit within the nappe succession (Table 2).

The difference in interpretation is, in effect, largely one of amount of later granite present. Our samples come from a deep borehole (S636) from the northern part of the area underlain by Mont d'Or formation where both authors agree to the presence of later granite. Thin sections of our samples show quartz, potash feldspar, sodic plagioclase, a small amount of chloritised biotite, and variable sericitisation of the feldspars.

Our results demonstrate a pre-3,400 Myr age not only for the Selukwe greenstone belt (Sebakwian group), but also for the nappe structure itself.

Table 2 Main stratigraphic units of the Selukwe greenstone belt, youngest formation at the top

After Stowe ⁵	After Cotterill ⁷
Small bodies of late granite	Mont d'Or formation (dominantly granite) with intrusive contact
Nappe tectonics	Nappe tectonics
Upper Greenstone formation	Tibilikwe formation (metabasalt with minor banded iron formation)
Wanderer formation	Wanderer formation (conglomerate and grit, overlain by banded iron formation)
Unconformity	Unconformity
Lower Greenstone formation (with serpentinites)	Selukwe Greenstone formation intruded by Selukwe ultramafic formation
Mont d'Or formation (dominantly meta-arenites)	

The eastern side of the Selukwe greenstone belt is cut by the Great Dyke (\sim 2,500 Myr). East of the Great Dyke, the metasupracrustals and chromite-bearing ultramafic rocks of the extension of the Selukwe greenstone belt occur tightly infolded with northerly trending banded gneisses and migmatites. Very similar rocks, again assigned to the Sebakwian group, and also tightly infolded with gneisses on a distinct northerly trend, occur farther east in the Mashaba area^{1,8}. Gneisses from the Tokwe and Shashe rivers near Mashaba have yielded a rather poorly defined age of $3,580 \pm 200$ Myr (ref. 2). East of Mashaba, the Mushandike granite, which intrudes similar gneisses, gave an age of $3,520 \pm 130$ Myr (ref. 9).

Thus our results from the Mont d'Or formation granite are in keeping with the regional picture of a \sim 3,500–3,600 Myr granite-gneiss terrain between Selukwe and Mashaba. In addition, they provide confirmation of the inference by Hawkesworth *et al.*² that the greenstone belt remnants within this terrain are also \sim 3,500–3,600 Myr old. The Selukwe greenstone belt is thus the largest preserved belt of this age known in Rhodesia. The possibility also arises that the Selukwe nappe structure is related to the tectonism which produced the prominent northerly trends in the gneisses between the Great Dyke and Mashaba.

The initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio of 0.711 ± 0.001 of the Mont d'Or granite is, as far as we know, the highest value yet recorded for such an ancient granite. The initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios for the \sim 3,500–3,600 Myr gneisses mentioned above are within the range 0.701–0.702. We provisionally interpret the high initial ratio of the Mont d'Or granite as indicating partial melting of earlier sialic crust, which need not necessarily be very much older. Thus, 3,600-Myr-old gneisses from the Shabani area, some 70 km S of Selukwe, have sufficiently high Rb/Sr ratios for their average $^{87}\text{Sr}/^{86}\text{Sr}$ ratio to increase by about 0.005 to 0.010 in as little as 200–300 Myr (S.M. and J.F.W., unpublished). It is possible that the Selukwe area is also underlain by ancient, high Rb/Sr crust of this type.

There is clear evidence for earlier granitic rocks in the pre-Mont d'Or Wanderer formation. Stowe³⁻⁵ and Cotterill^{6,7} record boulders and pebbles of various types of granite and gneiss in the conglomerate of this formation.

These could have been derived by erosion of 3,500–3,600-Myr-old basement similar to that exposed further to the south and east.

We thank R. Goodwin and M. Humm for technical assistance.

Monitoring the marine environment for mutagens

VARIOUS chemicals found in the environment are mutagenic when tested in an appropriate screening system¹, and some of them are deposited as waste in the seas and oceans, where they may or may not be deactivated. A means of monitoring the marine environment for the presence or absence of mutagens would give some indication of the efficiency of disposal of industrial waste products. In an attempt to minimise the technical problems, we have developed a biological assay for the detection of such pollutants.

Our assay detects mutagens in the tissue of the mussel *Mytilus edulis*, which is widely distributed in the tidal zone

and shallow coastal waters of the northern and southern hemisphere, and has been used in several studies of water pollution and interspecific relationships^{2–5}. Because of its mode of filter feeding and intracellular (phagocytic) digestion, this organism may concentrate marine pollutants within its body tissues and these provide a source of testable material.

Test samples were screened using auxotrophic yeast cultures to detect the induction of prototrophic colonies produced by mitotic gene conversion, a process of genetic change that responds to treatment by mutagens and carcinogens in a nonspecific manner⁶. Extracts were also exposed to cultures of both *Salmonella typhimurium* and *Escherichia coli* carrying genetic markers to detect forward and reverse mutation produced by both base-substitution and frameshift DNA changes.

Yeast cells were incorporated with mussel extracts and minimal selective medium in the presence of sufficient growth supplement to enable the cells to undergo three rounds of cell division. *S. typhimurium* was used in a plate incorporation system, as described by Ames *et al.*⁷. *E. coli* was used in both plate incorporation tests and modified bacterial fluctuation tests, as described by Green *et al.*⁸.

Alcoholic extracts were prepared from mussel samples collected from Plymouth (heavy visual pollution), Mumbles, Caswell Bay and Anglesey (clean water area), all in the United Kingdom. The results of exposure of yeast cultures auxotrophic for histidine and tryptophan to mussel extracts at concentrations up to 4% are shown in Table 1. Significant increases in the production of both histidine and tryptophan prototrophs were produced by mussel extracts from Plymouth, Mumbles and Caswell Bay, whereas no such increases were detectable in the presence of mussel extracts derived from the clean waters of Anglesey. Table 1 also contains the positive results of treatment in identical conditions with ethyl methane sulphonate, and the negative result obtained when alcohol was used as a control. Table 1 also shows the results of mussel extracts (Mumbles) derived from either liver tissue alone or non-liver tissue. When prepared in this manner, most of the genetic activity was found to be due to the non-liver extracts.

Table 1 Induction of mitotic gene conversion by mussel extracts

Treatment	Mean no. of <i>his</i> ⁺ prototrophs per plate	<i>his</i> ⁺ prototrophs per 10 ⁶ survivors ± s.e.	Mean no. of <i>trp</i> ⁺ prototrophs per plate	<i>trp</i> ⁺ prototrophs per 10 ⁵ survivors ± s.e.	% Viability
Control 1	8.6	26.8 ± 4.6	7.4	23.1 ± 4.3	91.4
Control 2	7.8	32.5 ± 5.8	5.2	21.7 ± 4.8	68.6
4% Alcohol control 1	6.5	25.6 ± 5.0	9.4	37.0 ± 6.0	73.1
4% Alcohol control 2	4.2	11.8 ± 3.0	7.6	21.4 ± 3.9	101.4
Plymouth extract 4%	202.6	493.6 ± 21.3	154.8	463.5 ± 18.6	95.4
Mumbles extract 4%	71.2	323.6 ± 19.2	85.3	387.7 ± 20.6	62.9
Caswell Bay 4% extract	69.0	276.0 ± 16.6	69.2	276.8 ± 16.6	71.4
Anglesey 4% extract	4.7	18.3 ± 4.2	7.6	29.6 ± 5.4	73.4
Mumbles liver 4% extract	10.8	40.0 ± 6.1	11.4	42.2 ± 6.3	77.1
Mumbles non-liver 4% extract	66.0	307.0 ± 18.9	123.2	573.0 ± 25.8	61.4
Ethyl methane sulphonate (1 µg ml ⁻¹)	284.7	900.9 ± 26.7	346.2	1,095 ± 29.4.7	90.3

Mussel samples were prepared by the extraction of 50 shelled mussels in 100 ml of 95% ethanol in a Waring blender. After centrifugation at 5,000g, extracts were filter sterilised and stored at 4 °C. Stationary phase cultures of the yeast strain *JDI*⁹, auxotrophic for histidine and tryptophan were suspended in saline at a concentration of 10⁷ cells per ml. Samples of mussel extract (up to 4%) were added to yeast minimal medium at 45 °C together with yeast cells at a concentration of 35 × 10³ cells per ml for detection of histidine independent prototrophs and 35 × 10³ cells per ml for detection of tryptophan-independent prototrophs and poured into 9-cm plastic Petri dishes. The culture medium was supplemented with 20 µg ml⁻¹ tryptophan and 0.1 µg of histidine for detection of histidine-independent prototrophs and with histidine (20 µg ml⁻¹) and 0.1 µg of tryptophan for detection of tryptophan independent prototrophs. These supplements enabled auxotrophic cells to undergo three cell divisions in the presence or absence of the mussel extract. All plates were grown in the dark at 28 °C and scored after 9 d of incubation. The possible nutrient effects of the Plymouth mussel extracts on auxotrophic yeast cultures were determined in two ways. (1) After incubation of plates as described above, disks of agar 9 mm in diameter were removed from areas of the selective plates showing background growth, but no large prototrophic colonies. Agar disks sampled from 10 plates per treatment were added to 20 ml of sterile saline and the yeast cells contained in the disks were suspended by sonication. After appropriate dilutions, the saline suspensions were plated on nutrient agar and viable cells were counted after 5 d of incubation at 28 °C. Comparisons of the viable cells contained in the background agar of both treated and untreated cultures indicated that there was no evidence of further growth of auxotrophic yeast cells in solid medium in the presence of mussel extract. (2) Samples of mussel extract were added to liquid minimal medium containing 10⁵ yeast cells per ml and the cultures were aerated at 28 °C for 24 h. Cell growth was determined by counting with a haemocytometer. In no case could we detect increased growth of cells in liquid medium in those cultures containing mussel extracts.

Table 2 Mutation induced in *E. coli* tester strains by MMS and mussel extracts as shown by the fluctuation test

<i>E. coli</i> strain	Locus	Treatment	No. of tubes sampled	Control tubes	Positive test	Significance (probability)

Fluctuation tests were carried out, with minor modifications, as described by Green *et al.*⁸. Overnight cultures of the *E. coli* tester strains were prepared in supplemented Davis-Mingoli minimal medium. After washing twice in saline, the cells were resuspended in saline at a concentration of 5.0×10^7 cells per ml. To 100 ml of Davis-Mingoli basal salts was added 10 ml of 40% glucose (for MMS), 0.1 ml of tryptophan (for liver tissue extracts) solution containing 200 µg per ml (for fluctuation tests involving tryptophan auxotrophs only) or 0.1 ml of lysine (for liver extracts) solution containing 200 µg per ml (for lysine auxotrophs only), 0.1 ml of washed cells, and in the case of the test treatments, either MMS to a final concentration of 1 µg per ml or 0.1 ml of alcohol mussel extract (liver or non-liver). Control experiments were conducted as for the test treatments but omitting MMS or mussel extracts. Controls for experiments involving mussel extracts also contained 0.1 ml of 96% ethanol. Each treatment was dispensed in 2.0-ml samples into 50 small test tubes and incubated at 37 °C. Once the auxotrophic bacteria had exhausted the small amount of supplement present, only prototrophic revertants continued to grow. From 2 d onwards, tubes in which mutation to prototrophy had occurred became turbid, while the other tubes remained relatively clear. The number of turbid tubes was determined routinely after 3 d. *E. coli* strains 343/113 and 343/113 *lys₆₀* were gifts from Dr G. Mohn and *E. coli* WP2 *uvrA* was a gift from Dr M. H. L. Green. To investigate the possible presence of free amino acids in mussel extracts that would increase spontaneous mutation rates by enhancing cell division, viable counts were made from individual cultures of *E. coli uvrA trp* (R46) obtained from fluctuation experiments with and without Mumbles mussel extract. It was found that the median number of bacteria per clear tube, that is tubes that did not contain *trp*⁺ revertants, was unaffected by the presence of mussel extract, and therefore Mumbles mussel extract did not enhance the growth of *trp*⁻ cells when the tryptophan supply has become exhausted. For tests involving the *galR₁₈^s* system, galactose replaced glucose in the fluctuation medium, also as this marker gives a high spontaneous number of turbid tubes each treatment was dispensed in 1.0-ml samples into 100 test tubes. The *arg₅₆* mutation is leaky and as a result some residual growth was observed even in the absence of arginine and therefore trace amounts of arginine were not added when it was used. L, liver, NL, non-liver, NS, not significant.

Table 2 shows the effects of both methyl methane sulphonate (MMS) and mussel liver and non-liver extracts on various strains of *E. coli* as measured by fluctuation tests. *E. coli* 343/113 *arg₅₆*, *nad₁₃₁*, *thi*, *lys₆₀* is a K12 strain developed by Mohn *et al.*¹⁰ for the reliable detection of different types of mutagen, utilising markers in the same genetic background. The *arg₅₆* mutation can be reversed, resulting in arginine prototrophy, by both base-change and frameshift mutagens; *gal R₁₈^s* is a forward mutation and the ability to use galactose as a carbon source can also be restored by both types of mutagen. *lys₆₀* reverts to lysine prototrophy predominantly after action by frameshift mutagens (personal communication from G. Mohn). *E. coli* WP2 *uvrA trp* is an *E. coli* B strain recommended by Green and Muriel¹¹ for base-change mutagen detection. The transferable drug resistance factor R46 has been shown to carry mutator genes that can enhance mutagenesis by both frameshift and base-change mutagens^{12,13}. R⁺ strains were constructed by conjugation using *E. coli* J6-2(R46) as a donor¹⁴.

All strains tested showed significant mutation in the fluctuation test after exposure to MMS. The *arg₅₆*, *gal R₁₈^s* and *trp* mutations all showed increased mutation frequency in the presence of 0.1% Mumbles mussel extract although as with the yeast experiments, in general, the non-liver fraction seemed to carry the major genetic activity. In contrast, the *E. coli* cultures carrying the auxotrophic marker *lys₆₀*, which carries a frameshift mutation, failed to show any increase in mutation frequency in the presence of

mussel extracts.

Table 3 shows the results of plate incorporation tests using both *E. coli* and *S. typhimurium*. Again the *E. coli arg₅₆* and *trp* loci showed significant reversion in R-factor-containing strains after exposure to mussel extracts. The *S. typhimurium his* mutants showed an increase in mutation frequency, induced by mussel extracts, in strain TA98, which produces prototrophic colonies by frameshift mutation, but not in strain TA100, which produces prototrophs by base substitution¹⁵. The failure of the latter strain to detect mutations induced by mussel extract reflects the specificity of the strains used.

Control experiments with both bacteria and yeast (briefly outlined in Tables 1 and 2), which will be described in further detail elsewhere, showed that the mussel alcohol extracts did not contain additional nutrient supplementation. Therefore the increases in prototrophs observed with the various strains were due to induction and not to a simple increase in cell division with a concomitant increase in spontaneous mutation. Further controls also showed that the mussel extracts were free of radioactive material.

Our results provide convincing evidence for the presence of mutagens that have become concentrated in the body tissues of mussels obtained from a number of maritime environments. The numerous observed correlations between chemicals showing convertogenic or mutagenic activity and carcinogenic activity¹⁵⁻¹⁷ suggest that such agents also represent a possible source of chemically induced carcinogenesis. At present our results do not provide direc

Table 3 Mutation induced in *E. coli* and *S. typhimurium* tester strains by mussel extracts as shown by plate incorporation tests

Strain	R factor	Mussel extract	Locus	Mean no. of prototrophs per plate
<i>E. coli</i> 343/113	—	Control	<i>arg</i> ₅₆	4.0 ± 1.0
		Mumbles (L)		9.0 ± 1.8

		Mumbles		22.0 ± 2.1
<i>S. typhimurium</i> TA100	+	Control	<i>hisG</i> ₄₆	163.8 ± 5.7
		Mumbles		174.0 ± 5.9

The method used was essentially that of Ames *et al.*⁷. Overnight cultures of the tester strains were washed in saline and resuspended in saline. Washed bacterial culture (0.1 ml) plus 0.1 ml of mussel extract were added to semimolten minimal agar at 46 °C containing glucose and relevant supplements. These overlays were poured over minimal media plates containing glucose. The plates were normally scored after 3 d of incubation at 37 °C. W, whole mussel extract; L, liver; NL, non-liver.

evidence of the nature of the chemicals we detected. But the active extracts came from mussels collected in areas with obvious industrial pollution or in close proximity to industrial areas.

We thank Professor J. A. Beardmore for introducing us to the biology of *Mytilus*, Mrs Margaret Clatworthy and Mrs Mary Lewis for technical assistance and Dr D. G. Wigham for constructive criticisms of the manuscript.

Species richness and stability of space-limited communities

ECOLOGICAL competition theory has reached its fullest state of development for the special case of competition for a renewable resource^{1,2}. There are, however, many instances of competition in nature to which this theory does not apply; for example, competition for space (*Lebensraum*). Because there are many space-limited organisms in nature, including many primary producers, this is an important gap in our theoretical under-

standing of ecological communities. Moreover, since the fundamental dynamic of competition for space—spatial mobility—is quite different from that of competition for a renewable resource, it would be unwise to try to extrapolate the theory of resource limitation to space-limited communities. In this paper, I outline some calculations, in the spirit of refs 3–7, which bear on the relation between stability and diversity for space-limited communities. (Full details will appear elsewhere.)

It is now widely accepted that in general mathematical models of multispecies communities, complexity *per se* tends to beget instability rather than stability (ref. 2, ch. 3). There are also traces of this tendency in space-limited communities, but for a certain class of space-limited communities, complexity (in the sense of species richness) promotes (local) stability.

The model used is a system of reaction-diffusion equations^{6,8,9} of the form

$$\frac{dx_i^\mu}{dt} = \left[C_i x_i^\mu \left(k_i - \sum_j a_{ij} x_j^\mu \right) \right] + \left[D \sum_v (x_i^v - x_i^\mu) \right] \quad (1)$$

The meaning of this equation is as follows (for a more detailed description, see ref. 6). The habitat is partitioned into *m* patches of space and is populated by *n* species; x_i^μ , $\mu \in \{1, \dots, m\}$, $i \in \{1, \dots, n\}$, is the number (or biomass) density of species *i* in patch μ . Within each patch, the species compete among one another according to (for the sake of concreteness) a Lotka–Volterra model. This is expressed by the first square bracket in equation (1), in which k_i is the carrying capacity for species *i*, the a_{ij} are the competition coefficients, and $C_i k_i$ is the growth rate of species *i*. The competition coefficients a_{ij} are chosen so that the corresponding Lotka–Volterra model allows no stable equilibrium with any pair of species present (which seems the most characteristic sort of competition for space). Each species is, however, allowed to disperse randomly among the patches at a rate characterised by a constant *D*; this dispersion is such that there will be a net flow of a given species from patches with a relatively high density into patches with a relatively low density of that species. This is expressed by the second half of equation (1).

Consider colonisation of newly available space in such a model, taking the following initial conditions: the *n* species are randomly distributed among the *m* patches, with only 1 species per patch, and its density is in each case near its carrying capacity. Using the above equations the system will, for sufficiently small *D*, approach a stable equilibrium, with all species present in each patch⁶. I will call this a ‘colonisation equilibrium’ of the model.

The stability behaviour of an equilibrium can be characterised by means of the quantity $\Lambda = \text{minimum} \{ -\text{Re}(\lambda_A) \}$, where $\{\lambda_A: A = 1, \dots, mn\}$ are the eigenvalues of the linearised stability matrix of the system, evaluated at the equilibrium². ($\text{Re}(z)$ means the real part of *z*, for any complex *z*.) The condition for stability in the sense of Liapunov is $\Lambda > 0$ (which is just the familiar condition that all the eigenvalues have negative real parts), but the magnitude of Λ contains additional information: in case the equilibrium is Liapunov stable, then Λ^{-1} is of the order of the time scale for the exponential return of the system to equilibrium, if it has been moved away from equilibrium by some (small) disturbance. Alternatively, if the effects of random environmental fluctuations are represented by taking some parameter in the model to be a Gaussian random variable with variance σ^2 , then an approximate criterion for ‘stochastic stability’ of the equilibrium (meaning that the environmental fluctuations are unable to drive the system very far from equilibrium) is $\Lambda > \sigma^2$ (refs 2, 10). Thus, among Liapunov stable equilibria, Λ is a meaningful measure of the degree of stability: the larger Λ , the more stable the equilibrium.

To determine how the stability of colonisation equilibria of the above family of models depends on the number, *n*, of colonising species systems with different values of *n* are needed

Fig. 1 The average (for the statistical ensemble defined in the text) largest real part of the stability matrix eigenvalues against \sqrt{n} , calculated by a numerical Monte Carlo method, for the parameter values $m = 1,000$, $D = 0.0002$, $(a, b) = (1.1, 1.9)$. The error bars are for one standard deviation. For systems chosen entirely at random, this quantity increases with n , rather than decreasing as here (ref. 2, Fig. 3.6).

which are, however, comparable in an appropriate sense. First, for a fixed habitat, the number, m , of patches is fixed throughout the following discussion. For each value of n , consider the statistical ensemble of systems having this number of species, for which the various parameters of the system are chosen at random from some fixed intervals of real numbers, and the n species are initially distributed at random among the m patches, with one species per patch. The average value of Λ is calculated for each n for the ensuing colonisation equilibria over this ensemble, and is $\langle \Lambda(n) \rangle$. The function $\langle \Lambda(n) \rangle$ of n indicates how, on average, the stability of such systems varies with n .

It transpires that there are two possibilities. Let (a, b) be the interval from which the competition coefficients α_{ij} ($i \neq j$) are chosen. Normalising α_{ii} to one for all i and scaling the species densities so that the carrying capacities k_i are all equal to unity, the condition for instability of all pairwise interactions (without dispersion) is $\alpha_{ij} > 1$ for all i, j with $i \neq j$. (This assumes no functional dominance, which will be discussed elsewhere in these pairwise interactions.) $1 < a < b$ must always be the case. The choices made for the other parameter intervals do not affect the qualitative nature of the outcome, which is as follows. If $a > 2$, then $\langle \Lambda(n) \rangle$ is a monotonically decreasing function of n , and if $(a+b)/2 < 2$, then $\langle \Lambda(n) \rangle$ is a monotonically increasing function of n .

Figure 1 shows an example of this latter behaviour (with $(a, b) = (1.1, 1.9)$). To facilitate comparison with earlier results² for stability matrices chosen completely at random, I have plotted the average largest real part of the stability matrix eigenvalues (that is, $-\langle \Lambda(n) \rangle$) against \sqrt{n} . The error bars are for one standard deviation. Figure 1 compares directly with Fig. 3.6 of ref. 2: the numbers depicted were obtained by a Monte Carlo method.

So, for $a > 2$ (which means roughly that the competition is constrained to be sufficiently "strong") increased species richness tends to destabilise the colonisation equilibria, whereas for $(a+b)/2 < 2$ ("weak" competition) increased species richness tends to stabilise the colonisation equilibria. The implications of this for the overall stability of the system depends on the global structure of each model. For some models, stochastic instability of the colonisation equilibria, in the sense that the variance σ^2 of environmental fluctuations exceeds Λ , will mean that the spatial structure of the system will be fluctuating constantly from one pattern to another, but with all n species present (compare ref. 7); whereas for other models it will mean

a high probability that one or more species will become extinct, on an ecological time scale.

I thank Alan Held, Robert May and Karin Yodzis for discussions.

Effects of drought on grain growth

DROUGHT severely decreases grain yield in many cereal growing regions and the resulting fluctuations in world food supply have serious repercussions¹. Crop breeders and physiologists are therefore studying varietal characteristics that may enable cereals to yield more consistently in drought conditions². Very few precise field measurements show how drought affects grain growth, but procedures have been advocated to provide a more precise description of grain growth and a more rigorous examination of sources of assimilate used for grain growth³⁻⁵. We have used these procedures to analyse how the droughts of 1975 and 1976 affected grain growth of wheat crops in England and to define particular physiological traits which govern yield.

The analysis is based on detailed measurements of crop growth made on three crops of Maris Huntsman winter wheat, grown in the Midlands on the same soil type in 3 consecutive years. The crops were grown according to normal agronomic practice and were chemically protected against diseases, pests and weeds. Actual evaporation (E_a) was measured using a neutron probe technique⁶ and potential evaporation (E_p) was estimated from a standard formula⁷. Table 1 gives the grain yields of the three crops and pertinent weather observations: 1976 was the driest growing season at Sutton Bonington since records began in 1916. E_p and temperature during grain growth increased markedly from 1974 to 1976, whereas E_a decreased.

For analysis, grain growth rate can be assumed constant^{3,8,9} and final mean weight per grain ($\bar{W}_g(f)$) can be expressed as:

$$\bar{W}_g(f) = \bar{W}_g(i) + (R_g \times D_g) \quad (1)$$

where $\bar{W}_g(i)$ is the initial value of \bar{W}_g , R_g is the grain growth rate during the linear phase of growth and D_g is the duration of that phase³. Increase in \bar{W}_g was assumed to be linear once \bar{W}_g exceeded 6 mg, and Fig. 1 shows the grain growth pattern

Fig. 1 Increase in mean weight per grain with time in 1974 (\square), 1975 (\triangle) and 1976 (\circ).

Table 1 Grain yield, weather and grain growth observations for the three wheat crops

Year	Dry matter grain yield* (g m ⁻²)	Duration (d)	Anthesis until cessation of grain growth		E_a/E_p	During linear grain growth				Final mean weight per grain (mg)
			Actual evaporation [E_a] (mm d ⁻¹)	Potential evaporation [E_p] (mm d ⁻¹)		Mean air temperature (°C)	Mean maximum air temperature (°C)	Mean grain growth rate [R_g] (mg d ⁻¹)	Grain growth duration [D_g] (d)	
1974	495 (46)	45	3.0	3.0	1.00	14.9	19.5	1.41	32.9	52.2
1975	535 (51)	38	2.0	3.4	0.59	16.8	21.6	1.76	25.2	50.3
1976	340 (32)	25	2.1	4.6	0.46	20.7	28.5	2.11	14.5	36.6

*Farm yields in cwt acre⁻¹ at 15% moisture are shown in parentheses.

for the 3 yr. Table 1 gives the relevant values of the variables of equation (1). Compared with 1974 the warmer, drier weather of 1975 was associated with a slightly faster R_g but this was offset by a decrease in D_g so that $\bar{W}_g(f)$ was close to 50 mg in both seasons, a typical figure for Maris Huntsman¹⁰. In 1976 very dry weather and exceptionally high temperatures were associated with very fast R_g (Table 1). But this was more than offset by a sharp decrease in D_g so that $\bar{W}_g(f)$ was only 37 mg.

Changes of plant dry weight after anthesis must be examined in greater detail to establish the reason for the extremely short D_g in 1976.

It is convenient to distinguish two sources of assimilate supply for grain growth: photosynthesis after anthesis, and translocation of materials assimilated before anthesis and temporarily stored before moving to the grain. As a first step in assessing the importance of these two sources, increase in grain weight from anthesis to final harvest (ΔW_g) can be expressed as

$$\Delta W_g = \Delta W_t - \Delta W_s$$

where ΔW_t is the increase in total crop weight, and ΔW_s is the increase in weight of plant parts other than the grain between anthesis and harvest⁵. By far the largest proportion of ΔW_s consists of the stem and for brevity this term is referred to as stem weight. In Table 2, which shows the relevant crop dry weight changes, $-\Delta W_s/\Delta W_g$ is the fraction of final grain weight apparently derived from translocation of materials assimilated before anthesis. Even in 1974, this fraction (0.35) was much larger than the maximum of about 0.20 expected for wheat¹¹. In 1975 and 1976, however, when production of dry matter after anthesis was smaller still in relation to the requirements for grain growth, the contribution of translocated materials to grain yield was much greater. This increased movement of materials from stem to grain when conditions during grain filling are adverse for photosynthesis lends support to the concept of "compensatory translocation"⁵. The small value of $\bar{W}_g(f)$ which occurred in 1976 in spite of considerable translocation of material from the stem raises two questions: is there a limit to the amount of dry matter that can be supplied to the grain by compensatory translocation; was this limit reached or exceeded in 1976?

The extent of translocation may ultimately be limited by the need to retain sufficient dry matter in the stems to support the ears. In 1976, however, supporting tissue per grain was considerably greater than in 1975 (Table 2). Thus it seems that shortage of assimilate did not limit final grain weight by curtailing the duration of grain growth. There are two other possible reasons why grain growth stopped: either the transport

system to the growing grain was inadequate or starch synthesis stopped prematurely. Studies of translocation during wheat grain growth show little effect of water stress¹², but there is evidence that a fall in the synthetic capacity of the endosperm causes grain growth to stop¹³. In 1975 and 1976, the duration of starch synthesis could have been limited either by the effect of drought on plant water status or by abnormally high ear temperatures. The relative importance of these two correlated factors cannot be determined from our measurements, but related work in controlled environments indicates that temperature rather than water stress stops grain growth prematurely¹⁴⁻¹⁶.

These results illustrate the potential importance of translocation of material assimilated before anthesis to grain growth when current photosynthesis is limited by an adverse environment. They also establish the usefulness of treating grain growth as a linear process and expressing final weight per grain as a product of a growth rate and duration. If cereals are to yield well in regions where drought and high temperatures during grain filling are frequent, varieties must be bred which not only increase the rate but also sustain the duration of grain growth. Such characteristics would maximise the assimilate to be harvested in the nutritionally valuable fraction of the crop.

We thank Dr M. McGowan for the measurements of crop evaporation, the Royal Society (J.N.G.) and the ARC for financial support.

1976	341	149	-192	0.56	63

Predicting the course of Gompertzian growth

THE increase in volume or size with time that characterises many biological and physical systems is often well approximated retrospectively by mathematical 'growth curves'. In some cases, however, growth may be sufficiently complicated for it to be impossible to predict later portions of the growth curve if observations are limited to a few early points. We report here the development of a generalised approach to

Fig. 1 Hypothetical Gompertzian curves derived by solving equation (3) with various parameters A and B as follows: Curve I, $A = 0.4$, $B = 0.4/(\ln 100)$; Curve II, $A = 0.25$, $B = 0.25/(\ln 100)$; Curve III, $A = 0.4$, $B = 0.4/(\ln 75)$; Curve IV, $A = 0.25$, $B = 0.25/(\ln 75)$. Note that the early portion of the curve reflects parameter A and the later portion of the curve reflects the ratio of A/B .

the analysis of "Gompertzian" growth which enables accurate predictions of future growth for two model tumour systems. This mathematical method may be useful clinically, and expresses a property of biological growth that may be applicable to other systems.

The growth of most experimental neoplasms²⁻⁴, human populations⁵, normal embryos⁶, molluscs⁷, visceral organs^{8,9} and some human tumours¹⁰ are well described by the S-shaped curves used for actuarial purposes by Benjamin Gompertz in 1825 (ref. 1). The essential distinguishing feature of Gompertzian growth (Fig. 1), is some mechanism of feedback inhibition with increasing size, resulting in decremented exponential growth that achieves a limiting size asymptotically. Unfortunately, the relatively complicated form of the Gompertzian equation has tended to limit its general applicability, often resulting in the alternative use of less satisfactory exponential¹¹⁻¹⁴, summed exponential¹⁵, or other¹⁶ growth models. These other models however, are rarely applicable to an entire growth history, and are therefore insufficient for the purposes of predicting later growth.

A Gompertzian function is the simultaneous solution of the two differential equations

$$dN(t)/dt = K_1 \cdot N(t) \cdot G(t) \quad (1)$$

$$dG(t)/dt = -K_2 \cdot G(t) \quad (2)$$

where K_i is a constant > 0 , $N(t)$ is volume at time t , and $G(t)$ is a function entirely described by equation (2). The expression $K_2 \cdot G(t)$ can be thought of as the fraction of $N(t)$ that doubles in size during the instant dt . The solution of these equations is often written in the form

$$N(t) = N(0) \cdot \exp[(K_1/K_2) \cdot G(0) \cdot \{1 - \exp(-K_2 \cdot t)\}]$$

Since

$$G(t) = G(0) \cdot \exp(-K_2 \cdot t) = (K_2/K_1) \cdot \ln[N(\infty)/N(t)]$$

where $N(\infty) = \lim_{t \rightarrow \infty} N(t)$, an alternative form of equation (1) is

$$\begin{aligned} dN(t)/dt &= K_2 \cdot N(t) \cdot \ln[N(\infty)/N(t)] \\ &= A \cdot N(t) - B \cdot N(t) \cdot \ln[N(t)] \end{aligned} \quad (3)$$

where $B = K_2$ and $A = K_2 \cdot \ln[N(\infty)]$. The dependence of the pattern of growth of $N(t)$ on A and B is illustrated in Fig. 1. For a given $N(0)$, when A is constant, the early phase of growth (often referred to loosely as the exponential phase) is similar in spite of different values of B . Also, when A/B is constant, the later phase of growth (the plateau phase) is similar in spite of different values of A . Were A and B unrelated, knowledge of the early phase of growth of a particular system (tumour, organ, embryo, or population) would not enable an accurate prediction of the later phase, as the value of A , but not A/B , could be estimated from the early growth pattern. Similarly, measurements of late growth would provide an estimate of A/B but not A . On the other hand, if it were possible to estimate B from A , the entire growth pattern of an individual system would be predictable on the basis of measurements early in its growth history.

For eight cases of B-16 melanoma in BDF₁ mice and ten cases of transplantable mammary carcinoma 13672 in Fischer 344 rats, measurements of length (L) and width (W) were obtained during unperturbed growth from the time of transplant until the death of the host or the occurrence of tumour ulceration. Approximate tumour volumes (V) were calculated as the volume of revolution of an ellipse by the formula

$$V = (\pi/6) L W^2$$

The growth of these tumours (Fig. 2) demonstrates the variability typical of malignant proliferation.

For each tumour, the solution of equation (3) was fit using the method of least squares to the curve of volume as a function of time of growth starting from the hypothetical volume of a single cell. Examples of curves fitted to data for each tumour type are illustrated in Fig. 3. Each curve fit yields the two parameters, A and B , that completely describe the growth pattern

Fig. 2 The volume of eight examples of B-16 melanoma (—) and ten examples of 13672 carcinoma (---) plotted as a function of time from initiation of growth. The volume scale is arithmetic. The variability in growth pattern typical of neoplastic proliferation is evident.

for that tumour. As seen in Fig. 4, when $\exp(A)$ is plotted against $\ln(B)$ for all individuals of each tumour type, the relationship is found to be linear with correlation coefficients of 0.99 for B-16 melanoma ($P < 0.0000002$) and 0.96 for the rat carcinoma ($P < 0.000006$). This high degree of correlation between the transforms of A and B allows, for these experimental tumours, the accurate prediction of B on the basis of an estimate of A made from measurement of the early phase of growth of an individual tumour. Equation (3) may therefore be written

$$dN(t)/dt = A \cdot N(t) - \exp[(\exp\{A\} - n)/m] \cdot N(t) \cdot \ln[N(t)] \quad (4)$$

a Gompertzian equation in one variable, A , with constants n , m , and $N(0)$ (the volume of a single cell) specific for a particular tumour type.

Having determined empirically the constants n and m for a tumour type, the total growth curve for an individual tumour of that type can be predicted accurately from a few early measurements of volume. In Fig. 3, for example, the solution of equation (4) was fit to three early measurements of a tumour not used to derive the above relationship between A and B . The prediction obtained is seen to match closely the actual volumes observed later in the growth of the tumour.

The ability to predict the later growth pattern of an individual tumour on the basis of early growth measurements should have widespread applicability, not only in the design of experimental anti-cancer therapy, but in the diagnosis and prognosis of human tumours as well. For example, the response of an individual cancer to treatment could be expressed in terms of deviation from ideal unperturbed growth as predicted from measurements taken before therapy. This precise method of monitoring therapy has obvious advantages over parameters presently in use, such as rate of complete or partial remission or average tumour size at some arbitrary point after therapy. These conventional endpoints are inapplicable to individual

Fig. 3 Examples of equation (3) fit to data for B-16 melanoma (\square) and 13762 rat carcinoma (\triangle). The volume scale is logarithmic. The dashed lines represent the fitted curves. Paired constants (A , B) derived from several such curve fits are plotted in Fig. 4. The points marked 0 are three early volume measurements for an individual 13762 rat carcinoma not used to derive the constants n and m (see text). Equation (4) was fit to these three points using constants n and m from Fig. 4; the resulting solid line is seen to predict accurately the later growth measurements (\bullet) for that tumour; measurements unknown at the time of curve fitting.

Fig. 4 Correlation between $\exp(A)$ and $\ln(B)$ for B-16 melanoma (\square) and 13762 rat carcinoma (\triangle). The points represent pairs of parameters (A , B) determined from curve fits as illustrated in Fig. 3; the solid lines represent the regression equation $\exp(A) = m \cdot \ln(B) + n$, with the following values of m , n , respectively: B-16 melanoma, 0.9645 and 4.980; 13762 carcinoma, 0.8176 and 4.334.

tumours, are potentially biased by drug or other non-tumour deaths, and may underestimate the influence of weakly effective forms of therapy which may nevertheless be potentially useful in combinations.

For these two experimental tumours the methods described here reveal a remarkable orderliness of growth that tends to dispel the concept of cancer as a wild and uncontrolled phenomenon. We may expect that the growth of non-neoplastic tissues (for example, gut epithelium, bone marrow and regenerating liver) would be at least as orderly as that of these two malignancies. Results obtained by applying these methods to normal tissues will be reported later. These mathematical methods may also be applied to the growth of mammalian or bacterial cells in culture, with obvious use in the monitoring of growth inhibitory influences (such as hormones and antibiotics). We also plan to describe the applications of these methods to other tumour types, paying particular attention to the description and prediction of the response of malignancies to single and multiple agent therapies.

Significance of cell shape in tissue architecture

STIMULI passing to a cell within solid tissue are modulated by the cellular environment. Control mechanisms must therefore involve both humoral influences and the architecture of the cellular microenvironment. Epidermis suffers a constant loss of surface cells which are replaced by basal cells which have differentiated during migration to the surface. In mouse ear and dorsum, the path of this migration can be observed as precisely defined columns of cells¹ which are in tetrakaidecahedral² form (Fig. 1) as in the rigid cell walls of plant tissues³. Recent studies^{3,4} have suggested that maintenance of this system of 'dynamic orderedness' may be explained by reference to its physical geometry, and minimal surface packing configurations. In this paper we discuss some of the consequences of this view of tissue architecture.

Fig. 1 a, Line drawing of an orthic tetrakaidecahedron. This 14-sided figure consists of six equal opposite quadrilateral faces and eight equal and opposite hexagons. Each quadrilateral face is bounded by four hexagons and each hexagonal face by three hexagons and three quadrilaterals. **b**, When compressed about a pair of hexagonal faces the shape assumed will become predominantly hexagonal, with the remaining 12 faces becoming hexagonal and quadrilateral facets around the edges.

The ordered epidermis of mouse ear or dorsum shows keratinised squames piled in columns and presenting a characteristic hexagonal patterning^{1,5}, when viewed from the surface (Fig. 2). It is clear from the flattened nature of these cells that if they are tetrakaidecahedral, then the orthic form of the tetrakaidecahedron has become distorted to a flattened version (Fig. 1), in which the flattening has resulted in an increase in area of a pair of the hexagonal faces, reducing the remaining 12 faces to alternate quadrilateral and hexagonal facets around the edges.

Fig. 2 a, Area of mouse ear epidermis showing a central hexagonal squame (1) and its six surrounding neighbours (2-7). Squame 1 is overlapped on all edges, and so cannot desquamate until all the surrounding cells (2-7) have done so, whereas squame 7 has all edges free and is able to desquamate. The region of overlap (previously covered by the last squame in the central pile) and the interdigitating facets are visible at the edges of the surrounding squames. At this advanced stage of flattening that occurs close to the surface, the facets at the squame edge have largely lost their characteristic alternate hexagonal and quadrilateral appearance because of the overall distortion, but still provide evidence of the tetrakaidecahedral form adopted in the less keratinised and more plastic regions of the granular layer. Scale bar: 5 μ M. **b, c**, Cells exposed from some distance below the surface showing clearly the facets at the edge providing the interdigitating regions. In some cells (**c**) a close approximation to the alternate hexagon (H) and quadrilateral (Q) faceting seen in the true geometric tetrakaidecahedron (Fig. 1b) is apparent. Scale bars: 5 μ M.

These facets may be observed in the scanning electron microscope particularly if some of the outer squames are removed (Fig. 2).

From the density packing configuration of either orthic or flattened tetrakaidecahedra, there is only one way in which these shapes can be assembled. This results in a columnar organisation in which the top 'cell' of the central column, of any group selected, occupies a position at the lowest or highest level, relative to the surrounding six adjacent columns which are

themselves subdivided alternately into two sets of three, each set at a different level (Fig. 3) rather than any of the other possible arrangements for hexagonal grid systems^{7,8}. Any individual surface cell may thus be considered to be surrounded by two sets of three, and as the individual itself is also part of a set of three, an entire area is thus split into sets of 'threes'. This approximates the observed structure of mammalian epidermis^{1,3,5,6} and was also suggested from a two-dimensional hexagonal grid system⁷ after consideration of control mechanisms.

Epidermal columns can be defined down to the spinous layer (Fig. 4) (that is the layer immediately above the basal layer) and each column must be maintained by vertical migration (and its associated cell division) in the group of 10 basal cells directly beneath the column as defined by the epidermal proliferative unit (EPU) concept^{5,6}. The cell kinetics of the epidermis⁹ suggest an entry of one cell per day into each column, which must equal the cell loss rate. Cell loss in a tetrakaidecahedral system is limited to individual cells, as each cell only becomes free to desquamate when it is slightly 'proud' of its six neighbours and has all its edges free (position 7 in Fig. 2a). Such an ordered desquamation in relation to tetrakaidecahedral cell shape implies a regular alternating overlap between neighbouring columns, as observed in epidermal sections^{6,7,10}. Communication between neighbouring columns seems necessary to ensure the correct sequence of cell migration⁷. Considered in profile alone (Fig. 4), for the regular alternating overlap of squame edges to be maintained, a column cannot introduce another differentiated cell into its squame pile until both neighbours have added to theirs. Extension of this concept to three dimensions involves consideration of the under surface of a group of seven tetrakaidecahedral columns (Fig. 3, inverted) and shows that the central column must be added to before those at the periphery. The overlaps of the peripheral columns may form a vertical channel to aid this sequence, and thus provide a partial self-assembly system which predetermines the column entered by the next migrating basal cell. This determination of the eventual position of each vertical migration imposes a sequence for cell migration and production on the basal layer. As there is a group of approximately ten basal cells positioned beneath each column (Fig. 4), it seems reasonable to assume that they provide cells directly into the column, as suggested by the EPU concept⁵: migration into a column from outside this group would be unnecessary and

Fig. 3 Drawing of a model of flattened tetrakaidecahedra assembled without interstices showing how the columnar arrangement develops. Three different levels are apparent in the group which consists of a central column (upper surface of the top cell black) and its surrounding six neighbours. The central column here is in the lowest position (black), the three columns arrowed right in the intermediate position, and the three arrowed left in the uppermost position. Thus when the diagram is inverted, the column ready to receive the next migrating basal cell will be the central column, and the raised edges of the six surrounding columns may provide a physical guide to facilitate such a migration.

Fig. 4 Diagrammatic representation of three adjacent columns and their underlying basal cells as seen in profile. Here the peripheral columns have been the most recent to add to their stack of differentiating cells so will not add further cells until the central column has added a cell, otherwise the exact overlapping of squame edges would not be maintained. No column or EPU is independent of its neighbours as regards the vertical migration of basal cells into the spinous layer.

inefficient, involving extensive lateral migration of basal cells. A problem thus arises with the direct comparison made by Menton^{3,4} between cell columns in epidermis and columns of soap bubbles. The epidermis is a compressed series of cell layers without intercellular spaces, tightly bound together by desmosomes. Migration from the basal layer involves a major change of cell shape and extensive breaking/remaking of the desmosomal contacts. In a bubble tank, however, there is free space for lateral movement, and no bubble-to-bubble connections, so any bubble may jostle its way to the correct position in a column base regardless of its point of origin. The basic difference is, therefore, that soap bubble columns exist as passively formed stable arrangements of randomly generated bubbles, in free space, whereas skin columns are produced by what can only be an active control of cellular dynamics.

Although the bubble analogy is useful in understanding the precise geometry of the system, it seems unlikely that living cells become formed into columns because they have no option other than to pack in a minimum surface configuration. It is more likely that selection in epidermis has produced the most efficient system of barrier production, which in stacked areas of epidermis assumes a minimum surface configuration. We may also mention at this point that in plantar mouse epidermis, there is no apparent order and also that the orderedness in stacked epidermis breaks down in response to wounding. In stacked epidermis it therefore seems reasonable to view each column as an individually controlled entity, with cell replacement occurring in the group of basal cells directly beneath the column, that is, an epidermal proliferative unit^{5,6}. Two levels of control of the EPUs would be necessary to maintain columnar organisation: an intra-EPU control of cell division as a replacement process subsequent to migration, and an inter-EPU control providing a synchrony of vertical migration in trios over the epidermal surface. It seems clear therefore that the ordered structure of columnar epidermis itself precludes random basal cell migration and mitosis, and suggests perhaps that other cell renewal systems with slightly less obvious cellular architecture may maintain themselves by similar systems.

Transformation of tissue-cultured xeroderma pigmentosum fibroblasts by treatment with *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine

In vitro transformation by chemical carcinogens has been shown and established mainly in rodent cells¹. Attempts made to transform tissue-cultured human cells have so far failed². Only two seemingly promising reports on *in vitro* transformation of human cultured cells were those reported by Benedict *et al.*³ and Rhim *et al.*⁴. But the cell line used by Rhim *et al.* to transform by treatment with *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG) was derived from osteosarcoma and had itself many cytological as well as chromosomal features characteristic of malignant tumour cells. As we cannot imagine why human cells should not be transformed by the chemicals which are potent carcinogens for cells of rodent origin, we believe that successful transformation depends only on finding the optimal experimental conditions and suitable cells.

Xeroderma pigmentosum (Xp) is a recessive hereditary disease characterised by a marked sensitivity to sunlight (ultraviolet irradiation) which often results in formation of skin tumours. This disease is due to a genetic defect of the excision repair system^{5,6}, analogous to the *uvr* mutations in *Escherichia coli*. We have been interested in this disease because it may help to clarify the mechanism of carcinogenesis by allowing the study of the relationship between the excision repair defect and malignant tumour formation. Here we report our preliminary results on an apparent transformation of fibroblasts derived from the skin of two Xp patients by treatment with MNNG.

A human Xp cell line designated CRL1200 was obtained from the American Type Culture Collection and used at 11th subculture level. This cell line was derived from an 11-yr-old girl with neurological complications and skin tumours in addition to ordinary skin symptoms characteristic of Xp; it had a normal fibroblast morphology. Another Xp cell line designated Xp-T was our isolate from a healthy part of skin derived from a 32-yr-old Japanese male with lip cancer in addition to ordinary clinical symptoms of Xp; it was used at its 9th subculture level. As a normal control a fibroblast culture derived from a 26-yr-old Japanese male without any positive reason to suspect genetic abnormalities was used at its 10th subculture level and was designated as Non-Xp.

Growth and maintenance medium consisted of Eagle's minimal essential medium (MEM) with 10% foetal bovine serum, 100 units of penicillin and 50 µg kanamycin ml⁻¹.

One day before MNNG treatment, cells were trypsinised at their confluent monolayer stage in Falcon 250-ml plastic flasks and 20% of them were discarded, to obtain cells growing actively at the time of MNNG treatment. After growth for 24 h in an atmosphere of 5% CO₂ in air at 37 °C, cells were again trypsinised and resuspended into the original volume of medium containing MNNG at 1 × 10⁻⁵ M. MNNG was dissolved in a minimal amount of dimethyl sulphoxide and then growth medium was added to give the concentration which was equivalent to the 10% killing dose as judged by the nigrosin vital staining against Non-Xp cells under the conditions employed for MNNG treatment. After 60 min treatment with MNNG in a CO₂ incubator at 37 °C, cells were centrifuged at 750 r.p.m. for 10 min, washed with

fresh medium and then inoculated at 1 × 10⁶ cells per 15 ml medium per flask. The treated cultures were then grown in a CO₂ incubator with medium change twice a week. After 26 d incubation, cells were trypsinised to respread in the same flask, and further grown with a similar schedule of medium change. On the 32nd and 39th days, one flask of the cultures was subcultured into two flasks.

On the 43rd day the MNNG-treated CRL1200 culture produced several focus-like spots which still consisted of spindle-shaped cells, although their arrangement was altered and criss-crossed. The MNNG-treated Non-Xp cells showed a similar morphological alteration up to this stage but reverted to the normal arrangement soon after. The arrangement of some of these focus-like spots in the MNNG-treated CRL1200 culture only changed progressively and randomly oriented multilayers began to form around the centres of the spots on about the 63rd day. But constituent cells still had a spindle-shaped fibroblast appearance. On the 77th day multilayer formation at the foci became more and more marked until under a microscope cells on the top of each focus could no longer be observed simultaneously with the cells around the focus directly attached to the flask surface. Cells on the top of foci lost the fibroblastic appearance and were converted into small epitheloid cells with only one to two nucleoli, round or polygonal cytoplasm and an ovoid or round nucleus. The peripheral area around these foci was also altered to consist of a criss-crossed cell arrangement where giant cells supposedly formed by nuclear fusion were often observed, and made a marked contrast to the unaffected outer area which consisted of fibroblasts with monolayer orientation.

The multilayered foci were formed only in the MNNG-treated CRL1200 culture but never in the untreated CRL1200 nor in the MNNG-treated Non-Xp culture. These cultures were trypsinised on the 85th day and chromosome counts were made. Only the MNNG-treated CRL1200 culture with marked multilayered foci showed polyploidy and heteroploidy although the majority of cells in these cultures remained unaffected and grew normally as spindle-shaped cells. No marked change in chromosome counts was observed in the untreated CRL1200 culture.

On the 105th day after the MNNG treatment, cultures were trypsinised and distributed into several flasks at a cell concentration of 1 × 10⁴ per flask. Then the increase in cell number and the percentage of cells in the S phase (as demonstrated autoradiographically by daily incorporation of ³H-thymidine (0.2 µCi ml⁻¹) following 24-h pulse labelling) were examined. As shown in Fig. 1, the MNNG-treated CRL1200 culture showed a higher cell saturation density than did the MNNG-treated Non-Xp culture. DNA synthesis in the MNNG-treated CRL1200 culture was observed

Fig. 1 Increase in cell number (solid line) and percentage of cells in the S phase (dotted line). a, Non-Xp; b, CRL1200 (Xp).

in 55% of the cells at saturation cell density but it was only 5% in the MNNG-treated Non-Xp culture. These observations suggested that the "transformed" CRL1200 culture, although still containing a large number of unaffected cells, consisted of cells showing "contact inhibition" less markedly than similarly treated Non-Xp cells. This was also confirmed in an autoradiogram which demonstrated that many of the cells constituting multilayered foci were in the S phase and that even the peripheral cells with monolayer orientation and fibroblastic appearance were actively synthesising DNA whereas unaffected cells incorporated almost no ^3H -thymidine label. Similar results to those described above for CRL1200 were obtained in another Xp strain, Xp-T.

These MNNG-treated transformed cells were examined three times for malignancy by transplantation into athymic nude mice which resulted in regression. Although tumorous growth was initially observed, histologically no sarcomatous pattern was shown. If the above described alteration in Xp cells after treatment with MNNG can really be considered as transformation, then it follows that only the Xp cells can be transformed by treatment with MNNG under the conditions employed but Non-Xp cannot. It had already been reported⁷ that cells from an Xp patient showed a higher frequency of transformation by SV40 than cells from the mother of the patient heterologous for the Xp gene. These observations suggest the interesting possibility of a common biochemical step between viral and chemical carcinogenesis and that this step itself is somehow affected in Xp patients.

Distribution and valency of receptor for IgE on rodent mast cells and related tumour cells

MONOMERIC IgE binds tightly to the surface of mast cells and basophils without, by itself, causing any known perturbation. Interaction of the IgE with an appropriate antigen (or experimentally with anti-IgE) causes the cells to degranulate. Little is known about the initial molecular events in IgE-mediated triggering, but there is considerable evidence that crosslinking of the IgE molecules is a critical step (see refs 1 and 2 for discussion). The available data suggest that only limited bridging rather than an aggregation-induced extensive redistribution of the surface IgE^{3,4} is required; indeed if the bridging is extensive enough to induce such gross redistribution within the time that degranulation would ordinarily be expected, the latter is inhibited^{3,5}. Since bridging of the IgE, and therefore of the receptor to which it is bound, seems to be a critical signal, it is important to know if the cellular binding sites for IgE are integrated into larger functional units; the receptor molecules themselves

might be multivalent, or individual receptors might be connected to each other by some other component (Fig. 1). The experiments described here were directed towards investigating this point. We saturated cells with a mixture of two distinguishable types of rat IgE and determined whether by redistributing one of them with specific antibody, the other would comigrate.

Rat IgE was purified⁶ from the ascitic fluid of rats bearing the IgE-producing immunocytoma IR162 (ref. 7). Fluorescein-labelled IgE (F-IgE) was prepared by reacting 10 mg ml⁻¹ of IgE with 2 mg ml⁻¹ fluorescein isothiocyanate, adsorbed on celite⁸ at pH 9.6 for several days. After centrifugation the solution was passed over Sephadex G-25. The final preparation which was fully active (as determined by comparing it with native IgE for its capacity to inhibit the binding of ^{125}I -IgE) had an average of 12 mol fluorescein per mol protein. Rhodamine-conjugated IgE (R-IgE) was prepared in an analogous manner (by Dr J. Schlessinger) and was similarly fully active.

The antisera used were as follows: rabbit anti-rat IgE was prepared as described previously⁹; anti-fluorescein antibodies were prepared from horse anti-fluorescein serum¹⁰ (the gift of Dr D. W. Scott) by adsorption on a column of fluoresceinated bovine IgG-Sepharose 2B and, after washing, elution with 0.1 M acetic acid. Rabbit anti-fluorescein antibodies were prepared from rabbit anti-fluorescein serum¹¹ (the gift of Dr R. Cathou) in exactly the same way. Comparable results were obtained with both anti-fluorescein sera. The preparation of fluoresceinated sheep anti-rabbit IgG has been described previously³. The four types of cells studied were: normal rat mast cells, rat basophilic leukaemia cells, normal mouse mast cells and mouse mastocytoma cells (AB-CBF₁-MCT-1); their preparation has been described previously¹².

The principal experiments performed involved incubating the cells with a mixture (1:1-3:1) of F-IgE and R-IgE (total IgE concentration 10-15 $\mu\text{g ml}^{-1}$) with $\sim 1 \times 10^6$ cells ml⁻¹ for 60 min at 37 °C. The cells were washed once, taken up in one-tenth of the volume and reacted with $\sim 10 \mu\text{g}$ of anti-fluorescein (or anti-IgE) for 30-60 min at 37 °C and then examined with a Leitz Orthoplan microscope equipped with a Phloem incident light attachment, BG38 and KP490 exciting filters and a K530 suppression filter.

Cells pretreated with an excess of unconjugated IgE and then incubated as described always showed negligible green or red fluorescence. Cells reacted with the fluorescent IgE mixture and no anti-fluorescein or anti-IgE showed a diffuse distribution of both fluorescent chromophores (Table 1, experiment 1). The green fluorescence on cells reacted with the mixture of F-IgE and R-IgE and then with anti-fluorescein (Table 1, experiment 2) was distributed in multiple

Fig. 1 Three basic models of IgE receptor valency or integration which were explored by the experiments reported here. *a*, Receptors univalent and independent; *b*, receptors multivalent and independent; *c*, receptors univalent and connected. The experiments did not distinguish between *b* and *c* or a combination of *b* and *c*.

Table 1 Distribution of fluorescent IgE on rat and mouse cells

Type of experiment	Preincubation	Antiserum	Chromophore on IgE*	Topological distribution	
				Normal cells	Tumour cells
1	F-IgE + R-IgE	—	F R	diffuse diffuse	diffuse diffuse
2	F-IgE + R-IgE	anti-fluorescein	F R	small patches, vesicles diffuse	small patches, vesicles diffuse
3	F-IgE + R-IgE	anti-IgE	F R	comigration of F-IgE and R-IgE in small and large patches	comigration of F-IgE and R-IgE in caps and large patches
4	F-IgE	anti-fluorescein followed by R-IgE	F R	— —	small patches, vesicles† diffuse†
5	F-IgE	anti-IgE followed by R-IgE	F R	— —	caps and large patches, some vesicles† comigration with F-IgE plus diffuse†

*F, Fluorescein; R, rhodamine.

†Only mouse mastocytoma cells tested.

small irregular patches which appeared to be on the surface of the cells, as well as multiple smooth-bordered vesicle-like forms which appeared to be inside the cells. Some of the latter had a non-fluorescent centre, giving a "doughnut-like" distribution of fluorescence. In some cases the patches and vesicles were distributed asymmetrically on and in the cell but rarely were larger patches or caps observed. There was never any redistribution of the red fluorescence (R-IgE); cells reacted with anti-fluorescein or buffer were indistinguishable in this regard.

Cells reacted with NaN_3 (0.2 M) or at 4 °C during incubation with anti-fluorescein showed the F-IgE to be distributed in patches, but no vesicular forms were observed. When cells were first reacted with anti-fluorescein at 4 °C and the temperature was then raised to 37 °C, the vesicles appeared and became maximal within 15–20 min. As before, the red fluorescence never showed any redistribution.

Cells incubated with the F-IgE and R-IgE mixture and then with anti-IgE (Table 1, experiment 3) showed a different pattern; in all cases, the F-IgE and R-IgE comigrated. The basophilic leukaemia cells and mastocytoma cells showed extensive capping and large patch formation. The rat mast cells showed small or larger patches and only very rarely a fluorescent cap. The small mouse mast cells showed some cap formation but the larger cells showed only coarse aggregation. Vesicle formation was rarely seen with any of the cells. A similar picture was seen with cells reacted with IgE (unconjugated or conjugated), rabbit IgE and fluorescent sheep anti-rabbit IgE: the tumour cells showed large patches and caps whereas the mast cells showed principally patch formation; again little vesicle formation was observed.

These experiments demonstrated that receptors binding R-IgE did not comigrate with the receptors occupied by F-IgE when the cells were treated with anti-fluorescein, but did so when reacted with anti-IgE. We used mouse mastocytoma cells to test what would happen to empty receptors when receptors with IgE bound to them were redistributed. Cells were reacted with F-IgE such that when an aliquot was tested with ^{125}I -IgE only 40% of the sites were found to have been saturated. The partially saturated cells were reacted with antibody for 1 h at 37 °C, washed once and then reacted with excess R-IgE. Cells reacted with anti-fluorescein (Table 1, experiment 4) showed marked vesicle formation and some small patches for the green fluorescence but the red fluorescence was diffusely distributed. The green fluorescence on cells reacted with anti-IgE (Table 1, experiment 5) showed marked capping, and a small amount of vesicle formation (this was the only experiment in which vesicle formation was observed with anti-IgE). The R-IgE partially comigrated with the F-IgE

but was also diffusely distributed in areas between the green patches. We interpret this as the result of binding of R-IgE to non-patched empty receptors as well as to empty combining sites on anti-IgE in the patches formed by anti-IgE complexed to F-IgE. Control cells untreated with antibody showed a diffuse distribution of both F-IgE and R-IgE.

The results of our experiments are consistent with the observations on the surface distribution of IgE as assessed by transmission electron microscopy using ferritin-labelled antibodies^{3,5,13}. Those studies showed that in conditions in which the antibody itself would not be expected to perturb the system, the IgE was diffusely distributed. Although it was difficult to rule out oligovalency of the receptors, there was no evidence for even bivalency, and multivalency was clearly not observed. Those experiments could not of course elucidate whether there was any connection between receptors (Fig. 1c).

The present results seem, however, to be in conflict with those of Ishizaka and Ishizaka¹⁴, who carried out the following experiment: human basophils partially saturated with human IgE were reacted with anti-IgE in conditions which led to gross surface redistribution of the IgE. The cells were acidified in conditions where a substantial proportion of the cell-bound IgE-anti-IgE complexes seemed to be dissociated. The neutralised cells were then reincubated with radioiodinated IgE and the surface distribution of the radiolabelled IgE examined by autoradiography. Another portion of the cells was first saturated by added unlabelled IgE before the addition of the anti-IgE. Significantly, the two populations of cells showed a similar distribution of grains, over 50% of the cells showing either a capped or grossly asymmetric distribution of the label. These results, which suggested comigration of 'empty' receptors with receptors to which IgE was bound, were interpreted as "... that a group of receptor sites are associated with each other at the cell membrane or that receptor molecules on [the] basophil membrane are multivalent with respect to the combining sites for IgE"¹⁴. That is, models 1b and/or 1c were favoured: our data are only consistent with 1a (Fig. 1) and we are uncertain about the reason for this apparent discrepancy. Among the possibilities are (1) that the difference results from the use of cells from different species (human as opposed to rodent); (2) the use of different cells (basophils as opposed to mast cells); (3) that in spite of having several controls, the experimental results result from some artefact introduced by the nature of the protocol. The relative simplicity of our own experiments make us doubt that this has occurred in our studies, and so we conclude that, at least with regard to rodent mast cells

and related tumour cells, the receptors for IgE conform to the model depicted in Fig. 1a. We are not suggesting that the receptors are not interacting with other (sub-)membranous structures; indeed some results of studies on the diffusion of bound IgE in the plane of the membrane suggest that this may be true¹⁵. In the study by Schlessinger *et al.*¹⁵ it was similarly shown that the receptors for IgE are independently mobile and are monovalent.

Using non-ionic detergent it is possible to solubilise the cell-surface receptor for IgE in an active form¹⁶. Recent results indicate that such receptors are univalent with regard to their binding of IgE¹⁷. Together with the results reported here, these findings indicate that the receptor *in situ* is similar to the solubilised receptor, at least with regard to this important property.

Lateral motion and valence of Fc receptors on rat peritoneal mast cells

MAST cells and basophils bind monomeric IgE antibodies reversibly but tightly by way of specific Fc receptors on their surface. Limited bridging of bound IgE molecules by multivalent antigen or anti-IgE antibody releases stored granules which liberate histamine and other mediators of the allergic response¹. The interaction of receptor-bound IgE with antigen (or with anti-IgE antibody) and the consequent cellular response (degranulation) provides an excellent opportunity for exploring the role of the lateral mobility of defined receptors in the transmission of 'signals' across the plasma membrane. Degranulation requires a limited bridging of complexes; excessive aggregation inhibits this response^{2–4}. We therefore measured the lateral mobility of the unperturbed IgE–receptor complexes on rat peritoneal mast cells and the effects on mobility of conditions that induce or inhibit degranulation. We redetermined⁵ the valence of the IgE receptor and the extent to which the IgE–receptor complexes react with each

Fig. 1 Photobleaching recovery curves of mast cells labelled with *a*, R-IgE, $D = 1.8 \times 10^{-10} \text{ cm}^2 \text{ s}^{-1}$, f.r. = 75% (—); *b*, R-IgE and anti-IgE antibodies $D < 6 \times 10^{-12} \text{ cm}^2 \text{ s}^{-1}$, f.r. < 10% (---). In all experiments the small illuminated spot was exposed for 0.5 s to laser power of $\sim 1 \text{ mW}$. $D = (w^2/4\tau_{1/2}) \gamma$ where w is the e^{-2} radius of the focused Gaussian laser beam ($1 \mu\text{m}$); γ accounts for the amount of bleaching and the beam profile. In these experiments $\gamma \approx 1.3$ – 1.4 (ref. 8). Similar D and fluorescence recovery values were obtained for laser beam focused on the top or the bottom of the settled mast cells. Fixation with 3% glutaraldehyde for 1 h at 4 °C inhibited receptor motion.

other. Fluorescence photobleaching recovery (FPR) was used to measure the macroscopic lateral motion of fluorescent cell-surface components^{6–9}. We and others have used this or similar methods, to measure the mobility on cell surfaces of concanavalin A (con A) binding sites (which include various surface components) and nonspecifically labelled membrane proteins^{6,7,10–12}. The present work and a concurrent study of acetylcholine receptors on developing myotubes (Axelrod *et al.*, unpublished) are the first quantitative measurements of the lateral motion of specific cell-surface receptors.

The preparation of rhodamine- and fluorescein-labelled IgE (R-IgE and F-IgE) and of the antisera has been described elsewhere¹³, as has the procedure for obtaining the rat peritoneal mast cells¹⁴. The mast cells (at $10^6 \text{ cells ml}^{-1}$) were incubated with R-IgE or F-IgE or a 1:1 mixture of both, at a total IgE concentration of 20–30 $\mu\text{g ml}^{-1}$ for 45 min at 30 °C, then washed with Hanks' balanced salt solution (BSS), resuspended in 0.1–0.5 ml of BSS, and allowed to settle on glass microscope slides. In some experiments, 0.1 ml of mast cells preincubated with fluorescent IgE were treated with 10 μg of anti-fluorescein or anti-IgE antibody (sometimes in the presence of 0.01 M NaN_3 to prevent endocytosis) for 30 min at 37 °C, washed, and applied to a microscope slide. In FPR measurements a brief, intense, focused laser light pulse irreversibly bleaches the fluorescence in a small region ($\sim 3 \mu\text{m}^2$) of the membrane. The time course of recovery of fluorescence in the bleached region due to replenishment by fresh fluorophore from adjacent parts of the cell was recorded and the shape of the recovery curves showed that recovery is consistent with fluorophore diffusion on the cell surface⁸. Receptor

Fig. 2 Mast cells labelled with *a*, R-IgE; *b*, R-IgE and anti-IgE antibodies.

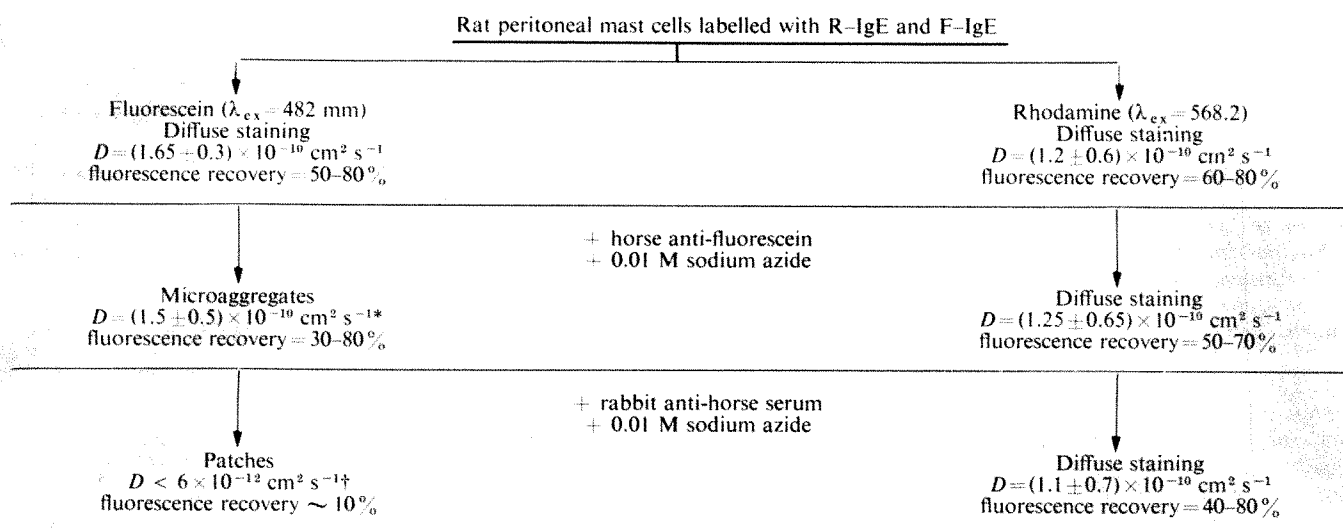

Fig. 3 Protocol for demonstration of IgE receptor valence. Mast cells were labelled with equal amounts of F-IgE and R-IgE. The values of D and f.r. and the fluorescence distribution were determined on individual cells independently for F-IgE and R-IgE by separate excitation of the two fluorophores using different excitation wavelengths. The left-hand column shows the protocol and results from detection of fluorescein; the right-hand column, from detection of rhodamine fluorescence on the same cell.

*Degranulation (G. Mendoza, unpublished).

†Inhibition of degranulation^{2,3}.

mobilities are, therefore, expressed as diffusion coefficients (D , $\text{cm}^2 \text{ s}^{-1}$) calculated from the recovery data. Incomplete fluorescence recovery is interpreted as indicating that a fraction of the fluorophores is immobile on the experimental time scale⁶⁻⁹. The fractional recovery (f.r.) therefore represents the fraction of mobile fluorophore⁶⁻⁹.

The mobility of dispersed IgE-receptor complexes is illustrated in Fig. 1, which shows a typical fluorescence recovery curve from a mast cell labelled with R-IgE. In this experiment, $D = 1.8 \times 10^{-10} \text{ cm}^2 \text{ s}^{-1}$ and the fraction of fluorescence recovery f.r. = 75%. The mean value and standard deviation for 17 cells was $D = (2.1 \pm 0.5) \times 10^{-10} \text{ cm}^2 \text{ s}^{-1}$ with f.r. in the range 50–80%. The division of the IgE-receptor complexes into mobile and immobile classes is interesting and although we cannot yet explain this heterogeneity, we have investigated factors which could influence it. We measured the diffusion coefficient of a fluorescent lipid probe (3, 3-diocadecylindocarbocyanine iodide⁷) in the plasma membrane of mast cells and found $D \approx 8 \times 10^{-9} \text{ cm}^2 \text{ s}^{-1}$, 40-fold greater than that of the IgE-receptor complexes. The phospholipid matrix is thus quite fluid, as has also been observed in rat myoblasts^{6,7}. The presence of immobile Fc receptors suggests that more than the fluidity of the phospholipid bilayer controls the receptor mobility. Sodium azide (10^{-2} M , 30 min) had no effect on fluorescence recovery, suggesting that the expenditure of metabolic energy was not involved. Colchicine (10^{-5} M , 45 min), which inhibits microtubule assembly, seemed to reduce f.r. to 20–50% but had no effect on D . In contrast, cytochalasin B ($25 \mu\text{g ml}^{-1}$, 45 min), which inhibits microfilament assembly, dramatically reduced the effective diffusion coefficient of Fc receptor to $D = (3.4 \pm 0.8) \times 10^{-11} \text{ cm}^2 \text{ s}^{-1}$, and reduced the f.r. to 20–50%. These three substances do not affect the diffusion of a lipid probe in either myoblast plasma membranes or planar lipid bilayers, demonstrating that the viscosity of the lipid matrix was not altered by the drug treatments⁷. Therefore we conclude that cytoskeletal interactions, especially with microfilaments, can influence the receptor mobility^{6,7}.

Treatment of mast cells prelabelled with F-IgE with a 10- to 50-fold excess (over receptor) of anti-fluorescein antibodies causes degranulation (G. Mendoza, unpublished). FPR measurements of the diffusion of F-IgE in these conditions yielded $D = (1.5 \pm 0.5) \times 10^{-10} \text{ cm}^2 \text{ s}^{-1}$ with f.r. from 40% to

80%. Fluorescent microaggregates, each $< 1 \mu\text{m}$ incorporating a substantial part of the total fluorescence, were visible on the cell surface. Similar results were obtained two hours after labelling. Aggregation of IgE to a level adequate for degranulation did not therefore, cause a detectable change in mobility. We cannot, however, exclude effective immobilisation of a small fraction of F-IgE.

In contrast, incubation of cells with anti-IgE antibodies (rather than anti-fluorescein) following labelling with F-IgE or R-IgE caused extensive redistribution of the complexes and large patch ($> 1 \mu\text{m}$) formation (see Fig. 2). FPR measurements carried out soon (15 min) after labelling indicated that the crosslinked receptors were essentially immobile; $D < 6 \times 10^{-12} \text{ cm}^2 \text{ s}^{-1}$, f.r. $< 10\%$. Diffusion of receptors is thus unaffected by the limited crosslinking by anti-fluorescein that is adequate for degranulation. Diffusion is, however, strongly reduced in conditions in which degranulation is inhibited by excessive aggregation with anti-IgE^{2,3}.

In the accompanying paper, Mendoza and Metzger¹³ show that anti-fluorescein antibodies induced redistribution only of F-IgE cells prelabelled with both R-IgE and F-IgE and so they concluded that the Fc receptor is monovalent for IgE. We have devised another sensitive experiment (Fig. 3) to test this conclusion, in which mast cells were labelled with equal amounts of F-IgE and R-IgE. The mobility of the fluorophores could be measured separately using krypton laser lines at 482 nm and 568.2 nm respectively. As expected, horse anti-fluorescein antibodies affected the mobility of neither F-IgE nor R-IgE. Addition of rabbit anti-horse antibodies, which bind only to the anti-fluorescein antibodies, caused patching and abolished the mobility of the F-IgE without diminishing the mobility of the R-IgE (see Fig. 3). This reinforces the conclusion of Mendoza and Metzger¹³ that the Fc receptor is monovalent and rules out the possibility that individual receptor molecules interact or are bound together to a significant degree⁶.

The major conclusions of the present study are: (1) Most IgE-Fc receptor complexes are mobile with $D = (2.1 \pm 0.5) \times 10^{-10} \text{ cm}^2 \text{ s}^{-1}$, but 20–50% are immobile on the experimental time scale. (2) Limited crosslinking by anti-fluorescein that is adequate for degranulation did not affect the apparent mobility of the receptors. Extensive aggregation inhibitory of degranulation, however, abolished the mobility. (3) The Fc receptor is monovalent for IgE. (4) Cytochalasin B reduces the

lateral mobility of the complexes; colchicine has little detectable effect.

Induction of an IgM anti-(bovine)-IgG response in mice by bacterial lipopolysaccharide

BACTERIAL endotoxin stimulates the appearance in mice of a large number of plaque forming cells (PFC) secreting an IgM globulin with specificity for bovine IgG (bovine gamma globulin; BGG). Reversed plaquing (antibody on the target erythrocyte) has enabled us to enumerate the total number of IgM secreting cells and show that the anti-BGG PFC comprise at least 10% of the total. Plaque inhibition with free antigen shows that anti-BGG PFC stimulated by LPS, as distinct from those specifically stimulated, secrete a product with low avidity. The evidence reported both here and in a previous study¹, leads us to suggest that substances such as LPS stimulate the production of an M-anti-G response. The rheumatoid-factor-like molecule which is produced may possibly serve to amplify complement fixation by high avidity/specificity IgG antibodies.

The injection into mice of certain substances apparently unrelated to sheep red blood cells (SRBC), can increase the level of 'background' antibody to SRBC, or the number of plaque forming cells producing antibody to SRBC²⁻⁴. Of such substances⁵ investigated, *Bordetella pertussis* (pertussis) organisms and water-in-oil emulsions containing heat killed mycobacteria (Freund's) can be readily classified as immunological adjuvants, and rabbit anti-(mouse)-lymphocyte globulin (ALG) as a mitogen lipopolysaccharide endotoxins from Gram-negative bacteria (LPS) combine the properties of both⁴⁻⁶. LPS stimulates not only an increase in cell growth and division *in vitro* but also the development of cells secreting antibody to SRBC and to the haptens NIP and NNP⁷. Since the mitogenicity of LPS is

confined to B-lymphocytes and since it also stimulates the production of antibodies with a wide range of specificities, including those specific for the antigenic moiety of LPS itself⁸⁻¹⁰, Möller and his colleagues coined the term PCBA—polyclonal B-cell activator—to describe substances with the properties just ascribed to LPS¹¹.

In the course of experiments designed to investigate the induction of tolerance to BGG in CBA/Ca mice, some animals received either an intraperitoneal injection of alum adsorbed BGG plus pertussis or an intravenous injection of

Fig. 1 Inhibition of anti-BGG plaques by free BGG added to the medium of the plaque assay. Each assay consists of 0.2 ml 1% Agarose-Eagle's basal medium plus target erythrocytes, PFC, and developing serum, spread into an area of about 25 × 50 mm on a standard microscope slide. *a*, Solid lines refer to plaques developed by a μ -specific developing serum on slides carrying spleen cells from CBA/Ca mice injected intraperitoneally 4 d before with either 20 μ g LPS (\blacktriangle ; 100% = 31×10^4 PFC/spleen) or intravenously with 1 mg HBGG (\blacksquare ; 100% = 2.3×10^4 PFC/spleen). The dashed lines refer to three separate experiments in which plaques were developed with a γ_1 -specific developing serum¹² using spleen cells taken 4 d after injection of HBGG (mean 100% = 1×10^4 PFCs per spleen). The solid symbols refer to data obtained on the same day. Each pool of spleen cells was prepared from five 8-10-month-old male mice. *b*, As for (*a*) except that all the data refer to anti- μ developed plaques. Mice were injected with either LPS (\blacktriangle ; 100% = 7.5×10^4 PFC per spleen), HBGG (\blacksquare ; 100% = 4.7×10^4 PFCs per spleen) or HBGG plus LPS (\triangle ; 100% = 19.3×10^4 PFC per spleen).

heat aggregated BGG (HBGG). The immune response of these mice was measured using a haemolytic-plaque assay, using as target cells, SRBC and SRBC coated with BGG by the chromic chloride method^{12,13}. When a rabbit anti-(mouse)- μ serum was being used in an attempt to inhibit direct plaques, it was found that this serum would enhance by about fourfold the number of plaques against BGG coated SRBC: the concentration of anti- μ serum used was one which had already been shown to be highly inhibitory to direct plaque formation by anti-SRBC PFC from the spleens of actively immunised mice. The developed plaques, which are very small, are an example of indirect IgM PFCs^{14,15}.

Subsequently, it has been found that such indirect IgM anti-BGG responses can be stimulated in CBA/Ca mice by the injection of pertussis alone, and even more so by LPS (*Salmonella typhosa* 0901 B). The maximum response is found 4 d after an intraperitoneal injection of 20 μ g of LPS.

The (indirect) anti-BGG PFC stimulated by LPS are judged to be IgM-producers on the following criteria. (1) Their numbers are enhanced by a rabbit anti-(mouse)- μ serum, raised, absorbed and tested for specificity as described previously¹⁶. Another such serum, kindly provided by Dr R. M. E. Parkhouse, gave an identical enhancement, which was abolished by passage through a μ -bearing Sepharose 4B column. (2) A goat anti-(mouse)- μ serum has been prepared which inhibits totally both direct anti-SRBC and LPS stimulated anti-BGG plaques. The difference in behaviour between the rabbit and goat anti- μ sera may be explicable on the basis of their differing abilities to fix the guinea pig complement used in the assay¹⁷. (3) The indirect anti-BGG plaques are ablated by reduction and alkylation procedures designed to destroy IgM but not IgG¹⁴.

The anti-BGG response, nonspecifically induced by LPS, is restricted in duration and in Ig class, although the number of PFC present in the spleen at the peak of the response, 4 d after the intraperitoneal injection of LPS, is quite high ($>10^5$ PFC per spleen). In contrast, the anti-BGG response, specifically induced by intravenous injection of HBGG, produces far fewer PFC per spleen ($<10^3$), and in addition induced both an early IgG (γG_1) peak 5 d after the injection, and a late IgG (γG_1 , γG_{2a} , γG_{2b}) peak 10 d after the injection of HBGG. The avidity for BGG of the antibody produced by PFC in the two types of response, has been compared (Fig. 1). A relative avidity can be deduced from the amount of free BGG required to reduce plaque numbers by an arbitrary proportion¹⁸, say to 32% of the

numbers detected in its absence. All PFC, irrespective of class, which were specifically induced by HBGG are inhibited by far lower concentrations of BGG than are the indirect PFC induced nonspecifically by LPS: it is concluded that the antibody induced by LPS has a very low affinity (avidity) for BGG. It is interesting to note that immunisation by a mixture of LPS and HBGG leads to an exceedingly heterogeneous population of PFC as judged by the shallow slope of the inhibition curve (Fig. 1b). This suggests that although they may overlap extensively, LPS and HBGG tend to stimulate different bands in the spectrum of precursor cells capable of becoming anti-BGG PFC. The nature of the inhibition curves and the numbers involved provide evidence that LPS stimulates a very much larger number of precursor cells than does HBGG. The possibility that LPS and HBGG stimulate some of the same precursors cannot be excluded on the evidence.

It is debatable whether LPS triggers B lymphocytes through being bound to Ig receptors for antigen. With the proviso that the polysaccharide (antigenic) moiety probably behaves like any other antigen, the lipid A (adjuvant) moiety may bind either to Ig receptors for antigen at positions other than the antibody-like site or, alternatively, to other (non-Ig) sites on the cell membrane. The triggering reflex may be the result of a cumulative effect exceeding some unspecified threshold, which results from the binding and perhaps crosslinking of a variety of membrane components: antigen, LPS and certain factors of lymphocyte or macrophage origin may well help to exceed this threshold. An hypothesis which suggests that antigen and adjuvant give qualitatively different triggering stimuli to antigen sensitive cells (ASC), thereby deciding between tolerance and immunity, has been discussed elsewhere¹⁹.

In passing, it may be worth noting the following points additional to the apparent differences in relative avidity of the IgM responses to BGG. (1) HBGG but not LPS stimulates an IgG response. (2) Secondary IgG (IgM?) responses stimulated by BGG after priming with HBGG can be demonstrated, but it has not been possible to demonstrate that LPS stimulates a secondary IgM response in mice primed either by HBGG or LPS. (3) In "tolerance" induction large doses of BGG (>1 mg) are required to reduce the level of IgM response but much smaller doses (<10 μ g) to reduce the level of IgG response¹³. (4) The magnitude of the peak anti-BGG response stimulated by LPS increases with increasing age of the mice up to about 8 months and thereafter remains more or less constant. There are no

*Cell counts were made with a model B Coulter counter windowed to exclude erythrocytes or smaller cells and cells the size of large blast cells or larger. As judged by Trypan blue exclusion cell viabilities are $>77\%$.

†SRBC coated with TNP at high epitope density by the method of Rittenberg and Pratt²¹.

‡A dash means that this target cell was not used in this experiment.

On the basis of these data, $4.0 \pm 0.43\%$ of spleen lymphocytes are secreting detectable amounts of IgM: of the IgM secretors $10.2 \pm 1.0\%$ are secreting anti-BGG antibodies, $8.2 \pm 1.9\%$ are secreting antibodies binding to TNP and only $0.22 \pm 0.07\%$ are secreting anti-SRBC antibody.

measurable changes in avidity to BGG of the IgM response induced by LPS over the age range of 2–20 months.

An estimate has been made of the total number of IgM secreting cells in the spleens of mice, both before and after the injection of LPS. The estimate was made using the technique of "reversed-plaquing"²² in which the target erythrocytes used in the plaque assay were coated with IgG from a goat anti-(mouse)- μ serum. An essential step was to develop the plaques by use of a rabbit anti-(mouse)- μ serum at the concentration used to enhance the level of anti-BGG plaques. Table 1 summarises the results of several experiments in which estimates have been made of the number of IgM secreting cells and the proportion of these cells which were secreting antibody reactive with BGG, sheep IgG, SRBCs and the hapten 2,4,6-trinitrophenyl (TNP). It is striking that, on the basis of these measurements, the anti-BGG response comprises about 10% and the anti-TNP about 8% of the total number of IgM secreting cells.

We think it is possible that the IgM response to BGG induced by an injection of LPS represents an unconventional immune response in which rheumatoid-like factors^{22,23} are secreted in response to stimulation by toxic products released by bacteria. In favour of this hypothesis are the facts that the response is IgM, low avidity and directed against an IgG molecule. The implication would be that to the CBA mouse, bovine IgG and bound or denatured murine IgG have similar antigenic determinants. So far however our attempts to demonstrate this directly using the plaque assay have been inconclusive. Nevertheless it has been possible to demonstrate that LPS stimulates the production of a humoral IgM (19S) which binds with relatively low avidity to mouse (γ G_{2a}) antibody bound to antigen (SRBC)¹. If our reasoning is correct, the high proportion of IgM secreting cells whose products have anti-IgG activity, could be regarded as a fast amplification mechanism which might be an adjunct to the complement cascade. The selective pressures influencing the evolution of this mechanism would therefore be quite different from those moulding high avidity responses to foreign determinants with a wide range of specificities.

We thank Dr J. H. Humphrey for a critical reading of a draft manuscript.

Immunological response restricts number of cells in sensory ganglia infected with herpes simplex virus

INFECTION of mice with herpes simplex virus (HSV) by various epithelial routes has been shown to result in a latent infection of the corresponding sensory or autonomic ganglia^{1–3}. During the acute phase of the infection (less than 14 d), virus could be recovered from ganglia both by homogenisation and explantation, while during the latent phase of the infection (21 d to more than 1 yr), virus could be recovered only by explantation and not by homogenisation. Although these methods made it possible to tell whether ganglia were infected, they gave no information about the percentage of ganglionic cells containing virus. We have therefore investigated the number of cells in sensory ganglia infected with HSV, and evaluated the influence of immunity on the severity of the infection.

HSV, type 1 (strain CHR-3), containing 2×10^8 plaque-forming units (PFU) per ml was prepared and assayed in primary rabbit kidney (PRK) cells⁴. Swiss athymic nude mice (Nu/Nu), normal littermates (Nu/+ or +/+) and BALB/c mice were infected with HSV by administering undiluted stock virus to the abraded right rear footpad². BALB/c mice were immunised with HSV by administering increasing doses of infectious virus (10^3 – 10^6 PFU) intraperitoneally at 10–14-d intervals, over 2 months. Previous experiments showed that the dorsal root ganglia (DRG) of mice did not become infected as a result of intraperitoneal immunisation⁵. Hyperimmune serum to HSV was prepared in rabbits by repeated intradermal injection (0.5 ml) of partially purified virus⁶. Neutralisation titres are expressed as the reciprocal of the highest dilution of serum producing a 50% reduction in viral plaques.

To determine the number of ganglionic cells infected with HSV, DRG were removed, washed in Dulbecco's phosphate-buffered saline (PBS) and incubated at 36 °C for 15 min in 2.0% collagenase (approximately 10 ganglia per ml). Tissue was aspirated gently four or five times with a Pasteur pipette, washed three times in trypsin-EDTA (0.25% trypsin in 4×10^{-4} M EDTA-saline), and then incubated at 36 °C for 15 min in the trypsin-EDTA solution. Foetal bovine serum was added to a final concentration of 10%. To eliminate extracellular virus, the ganglionic cells were

Fig. 1 Percentage of ganglionic cells infected with HSV at different times after infection. BALB/c mice were inoculated with HSV by the footpad route and DRG were removed and dissociated into single cells. Serial twofold dilutions of the cell suspension were placed on PRK cell monolayers and the percentage of infected ganglionic cells was determined.

Fig. 2 Effect of immunisation on number of cells in DRG infected with HSV. Immunised (●) and unimmunised (○) BALB/c mice were inoculated by the footpad route with HSV and at different times thereafter DRG were removed and dissociated and the percentage of infected cells was determined.

resuspended and incubated for 30 min in rabbit anti-HSV serum (50% neutralisation titre, 400). The cell suspension, containing primarily single cells, was washed five times to remove excess neutralising antibody, resuspended in PBS, and the viable cells were counted by Trypan blue exclusion. Based on staining for Nissl bodies⁷, we estimated that the final cell suspension contained 5–10% neurones. Supernatant fluid from the fifth cell wash was assayed to ensure that infectious virus was not present in the final cell suspension. Serial twofold dilutions of the cell suspension were placed on triplicate or quadruplicate monolayers of PRK cells. Cultures were examined daily for 10 d for the appearance of HSV cytopathology. Percentage of ganglionic cells infected was calculated (according to the method of Reed and Muench) by determining the number of dispersed ganglionic cells required to produce lysis of the PRK monolayers in 50% of the cultures (that is, based on the assumption that only one infected ganglionic cell was needed to initiate lysis).

DRG were removed from animals at different times after footpad inoculation with HSV, and the number of infected cells in ganglia was determined. Figure 1 shows that between 6 and 8 d after inoculation, almost 1.0% of the cells in the ganglia were infected. During the next few weeks, the percentage of infected cells decreased to 0.1% or less, and remained at that level for almost 15 months.

Earlier experiments showed that immunisation with HSV did not prevent mice from developing a latent infection when challenged by the footpad route³. To see whether immunisation affected the total number of ganglionic cells that became infected, immunised and unimmunised mice were challenged with HSV by the footpad route, and at different times thereafter the virus-infected cells in ganglia were counted. The data in Fig. 2 show that immunisation

restricted infection of ganglionic cells; approximately one-tenth the number of ganglionic cells was infected in immunised as in unimmunised animals. Moreover, the number of infected cells in ganglia of immunised animals during the acute phase of infection corresponded closely to the number of infected cells in ganglia of unimmunised animals during the chronic phase of the infection (Fig. 1).

Further evidence that the immune status of the host influences the number of cells infected in ganglia comes from studies with nude mice. Figure 3 shows that the number of infected cells in ganglia of nude mice (Nu/Nu) continued to rise during the first 10 d of the infection and reached close to 7.0%. In contrast, only 0.1% of ganglionic cells was infected in nude mice given antibody to HSV 2 d after HSV inoculation. Similarly, only 0.1% of the ganglionic cells was infected in phenotypically normal littermates of nude mice (Nu/+ or +/+) not given antibody to HSV. Thus, the nude mouse, which cannot mount an effective immune response to HSV⁸, has almost 70 times more HSV-infected cells in the sensory ganglia than the antibody-reconstituted nude mouse (Nu/Nu) or the phenotypically normal mouse (Nu/+ or +/+).

The studies described here show that by dissociating sensory ganglia, it is possible to determine the number of cells

Fig. 3 Percentage of ganglionic cells infected with HSV in immunologically deficient animals. Nude mice (Nu/Nu) and phenotypically normal littermates (Nu/+ or +/+) were inoculated by the footpad route with HSV. Two days later the nude animals were given intraperitoneally either 0.1 ml of normal mouse serum or 0.1 ml of mouse anti-HSV serum (50% neutralisation titre, 1,048). At different times thereafter DRG were removed and dissociated and the percentage of infected cells was determined. ○, Nude mice given normal mouse serum; ●, nude mice given mouse anti-HSV serum; △, phenotypically normal littermates of nude mice.

infected by HSV. Because of the potentially low plating efficiency of infected cells, as well as the possible loss of cells due to physical manipulation, the actual number of virus-infected cells in ganglia may be considerably greater than the 0.1–1.0% obtained in our experiments. Moreover, although our data are expressed as percentage of cells in ganglia infected with HSV, it was estimated that less than 10% of the cells plated were neurones.

Even though the assay used here may greatly underestimate the true number of cells infected, it does provide a useful method for comparing the relative number of cells infected in different experimental conditions. In this connection, we found that the number of infected ganglionic cells fell off sharply after the acute phase of the infection and remained relatively constant for many months thereafter. Whether this is due to two populations of cells in the ganglion susceptible to HSV—one capable of being lysed by the virus, and the other capable of maintaining a latent infection—or whether the immune response of the host destroys some of the virus-infected cells is not known. Our studies with immunised and nude mice, however, do show that the immunological status of the host is one of the factors that controls the number of cells in ganglia that becomes infected. Precisely how the immune response of the host restricts infection of ganglionic cells is not clear. It is known that HSV replicates in the skin and travels up the nerve to the cell body in the ganglion^{9–11}. Thus the number of nerve endings exposed to the virus may determine the number of cells ultimately infected. If the immune response of the host inhibits viral replication in the skin, the number of cells becoming infected would be reduced correspondingly. Alternatively, the virus may spread from one cell to another within the ganglion and the humoral and/or cellular immune response may act at this level¹². The demonstration in nude mice that passive administration of antibody is protective, suggests that humoral immunity plays a part in limiting the initial spread of the virus. Whether humoral immunity also is responsible for maintaining the latent state of the infection¹³ cannot be resolved from our experiments.

The demonstration that, in different experimental conditions, the number of infected ganglionic cells varies considerably, suggests that this might be an important factor in determining the subsequent clinical course of the disease. All other things being equal, the severity and frequency of recurrent HSV attacks might very well be related to the number of latently infected cells.

We thank Dr Kozaburo Hayashi and Mr Charles R. Wohlenberg for assistance.

A human chromosomal determinant for susceptibility to herpes simplex virus

THE susceptibility of mammalian cells to virus infection has been studied in many virus–host systems. In certain instances^{1–6}, the comparison of cells which do not permit productive infection with those that do has made it possible to identify the host factors which allow entry of the virus and support its subsequent growth. In the case of poliovirus the use of somatic cell hybrids between permissive and non-permissive cells has led to the assignment to human chromosome 19 of a gene coding for virus susceptibility⁷. Although cells from a wide variety of organisms, including many rodents and man, are susceptible to lytic infection by herpes simplex virus type 1 (HSV-1) resistance to HSV-1 infection has been reported in certain Chinese hamster cell lines^{8–10}, in dog kidney cells¹¹, and in a line of rat cells¹². In these cell lines HSV-1 is either non-infectious or exhibits virus titres several orders of magnitude lower than in Syrian hamster or rabbit cells. The cellular factors involved in this resistance to infection and in the genetic control of susceptibility to HSV-1 have not yet been identified.

We report here experiments in which Chinese hamster × Syrian hamster and Chinese hamster × human somatic cell hybrids were used as hosts for HSV-1 infection. The results indicate that susceptibility to HSV-1 infection behaves as a partially dominant genetic trait in these cells, and that its behaviour in Chinese hamster × human hybrids which are segregating human chromosomes is consistent with its being determined by the presence of human chromosome 3.

The results in Table 1 confirm the earlier finding⁹ that HSV-1 has low infectivity in Chinese hamster Don cells¹³ and show that genetically marked derivatives of Don are also less susceptible to HSV-1. As certain of the cell lines were unable to form complete monolayers, we used the 17 *syn* strain¹⁴ of HSV-1 in most of our experiments. This strain causes polykaryocytosis which results in the formation of easily recognised syncytial plaques. Where tested, essentially similar results were obtained with the *syn*⁺ parent strain. As can be seen, virus titres were at least 10⁴-fold lower on Don and its derivatives than on Syrian hamster BHK-C13 cells¹⁵. Reproducible virus titres on Don cells could only be obtained at multiplicities above 0.1 PFU per cell (as measured on BHK-C13 cells). The burst size in these conditions as measured by infectious centres and yield assays (approximately 150 PFU per infected Don cell) was comparable to that on BHK-C13 cells. The progeny virus

Table 1 Susceptibility of Syrian hamster and Chinese hamster cell lines to HSV-1 strains

Cell line	Virus titre (log ₁₀ PFU* ml ⁻¹)	
	HSV 17 <i>syn</i>	HSV 17 <i>syn</i> ⁺
BHK-C13	7.3	9.3
C13 TK ⁻	7.3	9.6
Don	2.3	5.2
Don TG 5.10 [‡]	2.5	5.6
Don TK ⁻ (a23)§	2.5	ND

Monolayers of each cell line in 50-mm plastic Petri dishes were infected with HSV 17 *syn* (low titre stock passaged in Lesch-Nyhan GM29 cells) or HSV 17 *syn*⁺ (high titre stock passaged in BHK-C13 cells). After 40 min incubation at 37 °C in Glasgow-modified Eagle's medium supplemented with 10% foetal calf serum, the inoculum was neutralised by the addition of an equal volume of medium containing 10% human serum. The neutralised inoculum was removed after a further 20 min incubation at 37 °C and replaced by medium containing 10% human serum. Incubation was continued for a further 48 h at 37 °C. Dishes were stained with Leishman stain and virus plaques counted. ND, not determined.

BHK-C13 TK⁻ and Don TG 5.10 (HGPRT⁻) cells were fused in monolayer¹⁷ using ultraviolet-inactivated Sendai virus (Searle Diagnostic Ltd), and complementing hybrid colonies isolated in modified²⁰ HAT medium¹⁸. Independent colonies were picked after 14 d, grown in plastic flasks (Nunc) to a total population size of 5×10^7 cells, and aliquots taken for karyotype and isozyme analyses or for storage in liquid N₂. Virus susceptibility tests were performed using HSV 17 *syn* as described in Table 1, on thawed cells which had been grown for one further passage. Chromosome numbers and the complement of Don chromosomes were determined by examination of Giemsa-banded²⁰ metaphase spreads.

*Range of values (90% limits).

†Don TG 5.10 is tetraploid.

‡1s indicates the presence of not more than 44 Chinese hamster chromosomes in the majority of cells.

produced did not, however, show an increased titre on Don cells.

The molecular basis for the low susceptibility of Don cells to HSV-1 infection is at present being investigated. Results not shown here indicate that, although adsorption and penetration of virus occur normally, there is little or no virus eclipse and viral thymidine kinase is not induced. We cannot at present, however, exclude the possibility that some early viral proteins are synthesised in Don cells infected at low multiplicity.

In order to determine whether susceptibility to HSV-1 is a genetically dominant trait, somatic cell hybrids were made between non-permissive and permissive cells. Cells of a Don HGPRT⁻ variant (Don TG 5.10) and a BHK-C13 TK⁻ variant were fused and complementing hybrids between them isolated under conditions designed to provide a series of hybrid clones of independent origin. These clones were tested at low multiplicities for their susceptibility to HSV-1. Table 2 shows that the Don \times BHK hybrids were susceptible to HSV-1 and gave virus titres 10^2 – 10^3 -fold less than the BHK parent. This result indicates that susceptibility

Lesch-Nyhan GM29 (HGPRT⁻) and Don TK⁻ (a23) cells were fused in monolayer (PF series) or suspension (GMA series) using ultraviolet-inactivated Sendai virus¹⁷. Complementing hybrids were isolated and analysed as in Table 2.

*Purchased from the Mammalian Genetic Mutant Cell Repository, Camden, New Jersey.

to HSV-1 behaves as a partially dominant trait. Although preferential loss of one parental set of chromosomes is not expected from these hybrids, it is clear that in some cases the average chromosome number in the hybrids is less than the sum of those of the two parents. Although we are unable to state conclusively that this was not due to preferential loss of chromosomes of one parent, there is no correlation between the extent of chromosome loss and susceptibility to HSV-1.

Hybrids were also constructed between a Don TK⁻ variant (a23) and human HGPRT⁻ skin fibroblasts from a Lesch-Nyhan patient (GM29). In this case the preferential and random loss of human chromosomes from such hybrid clones is well established¹⁹. A series of independently isolated Chinese hamster \times human hybrid clones were assayed for HSV-1 susceptibility as before (Table 3). As can be seen, partial dominance of susceptibility was demonstrated by six of the hybrid clones, while the remaining seven clones were non-susceptible. The susceptible clones gave titres approximately 10^2 – 10^3 -fold less than that of the human parent, which is in agreement with the 10^2 – 10^3 -fold difference between Don \times BHK hybrids and their BHK parent, whilst virus titres on the non-susceptible clones were similar to those obtained on Don. This result implies the existence of a partially dominant human chromosomal determinant for HSV-1 susceptibility which segregates out of the hybrids as human chromosomes are lost.

In order to determine the complement of human chromosomes

Table 4 Correlation between the presence of human chromosome 3 and HSV-1 susceptibility in Chinese hamster \times human somatic cell hybrids

Chromosome 3	HSV-1 susceptibility	
	+	—
+	6	0
—	0	7

Giemsa-banded metaphase spreads of Chinese hamster \times human hybrid clones were prepared as described previously²⁰. A minimum of 25 metaphase cells of each clone were scored for the presence of human chromosome 3; positive clones were those in which chromosome 3 was present in more than 50% of cells. The data on HSV-1 susceptibility were taken from Table 3. The table shows the number of clones found in each category.

in the hybrid clones, isozyme^{21,22} and karyotype analyses were performed. Using the technique of Cellophane electrophoresis the hybrids were analysed for the following isozyme markers: phosphoglucose mutase-1, isocitrate dehydrogenase, hexose-aminidase B, superoxide dismutase B, glutathione reductase, adenylate kinase-1, glutamic-oxaloacetic transaminase, lactate dehydrogenase A and B, nucleoside phosphorylase, pyruvate kinase, peptidase A, glucose phosphate isomerase, adenosine deaminase, superoxide dismutase A, and glucose-6-phosphate dehydrogenase. In no case was a correlation found between the presence of the human form of an enzyme in a hybrid and its susceptibility to HSV-1 infection, thus excluding by inference²³ a linkage to human chromosomes 1, 2, 5, 8, 9, 10, 11, 12, 14, 15, 18, 19, 20, 21 or X, respectively. Linkage to chromosome 17 is also excluded, since this chromosome carries the human thymidine kinase gene²⁴ which is required by all clones for survival in HAT medium.

Human chromosomes were readily distinguishable from those of the Chinese hamster in Giemsa-banded metaphase spreads of hybrid clones. Although extensive chromosome rearrangement was evident in one clone (PF4A1), in the majority of cases chromosome morphology was normal, and we were able to confirm the presence of those chromosomes whose presence was implied by the isozyme data. Of the remaining chromosomes only human chromosome 3 was present in all HSV-1 susceptible clones and absent from those which were non-susceptible. Although the total number of hybrid clones considered in this study is small the correlation shown in Table 4 is statistically significant ($\chi^2 = 6.20$; $0.01 < P < 0.05$), and we

therefore conclude that the gene(s) responsible for HSV-1 susceptibility in Chinese hamster \times human hybrids is located on human chromosome 3. The nature of the host factor(s) specified by this gene must remain the subject of further investigations.

We thank our colleagues Dr M. L. Hooper and Dr C. Slack for discussions, and Professors J. A. Pateman and J. H. Subak-Sharpe for their interest. Technical assistance was provided by R. H. M. Morgan, L. Meagher and P. Hoover. The 17 *syn* strain of HSV-1 was a gift from Dr N. Wilkie. The work was supported by a grant from the Cancer Research Campaign.

Influence of multiple syngeneic foetal heart grafting on individual graft survival

THE factors which influence many developmental phenomena are poorly understood. One would like to know, for example, how it happens that an organism only develops one heart. A possible clue to this particular question arose inadvertently from an immunological tolerance assay involving inter-strain grafting of murine foetal hearts into adult ear pouches¹. We noticed amongst the control syngeneic grafts that whereas single heart grafts had a high long-term survival rate, grafting two hearts into a single animal seemed to considerably reduce the individual graft survival rate. The experiments reported here extensively document this observation using different strains and different grafting sites, as well as control grafts for specificity.

The recipient animals used in the study were highly inbred CBA/J and BALB/Ccr males between 2 and 4 months of age and were obtained from our breeding facility at the University of Alberta. No animal of a given strain was more than four generations removed from the ancestral breeding pair generating any other animal of that strain. Pregnancies were timed by checking for the presence of vaginal plugs, and the day after plugging was labelled day 1. All grafts reported in the study were obtained from 17-d foetuses. The principal method of grafting consisted of preparing a pouch under the dermis of the ear with the aid of small sharp scissors and tucking the graft as deeply as

possible into the pouch. Vascularisation of the foetal heart in this position permits recording of the graft's electrical activity simultaneously with that of the adult heart by specialised electrocardiography¹.

The results of a large number of such grafts performed in two different strains and read over the course of a 10-week period are shown in Table 1. The data for the CBA/J strain indicate that grafts put singly into an animal have a much higher probability of functioning than do grafts placed in an animal along with a similar graft in the opposite ear. The effect is reasonably stable over 10 weeks and the differences between the groups for any individual week are quite apparent. For example, even at week 1 the difference is highly significant ($P < 0.0001$) when tested by the chi-square contingency method. The results with a different strain of mice, BALB/Ccr, are concordant, although the overall functioning of both single and double heart grafts is somewhat reduced. The differences, although not as striking, are significant and the effect seems to disappear with time due to reduced functioning of the single heart grafts. In addition, a third strain (CBA/CaJ) was tested using 14 single grafts and 14 double grafts and the results at 2 weeks are similar to the previous data (57% functioning single hearts and 21% functioning double hearts, $P < 0.05$).

One possible explanation for the reduced survival of double heart grafts is that the added time and trauma involved in grafting the second heart somehow compromise both grafts. In order to test this, hearts were grafted into the left ears and either 17-d foetal kidney or 17-d foetal testis explants were grafted into the right ears of a group of CBA/J recipients. The hearts were checked at 2 weeks by electrocardiographic activity and then the ears were sectioned to examine the survival of the foetal kidney and testis grafts. Table 2 shows that neither foetal kidney nor foetal testis significantly affected the functioning of the grafted hearts at 2 weeks post-transplantation. The effect, therefore, seems to be specific for foetal heart. In order to further rule out artefacts that might ensue from the site of grafting and the method of reading, heart grafts were placed under the kidney capsule and scored one week later for beating, using an operating microscope. A heart was scored as positive if any fasciculation whatsoever could be detected within 1 min of viewing. The single hearts were implanted in the left kidney capsule and the double grafts were implanted either in the same kidney capsule or the contralateral kidney capsule. Since neither of these two situations differed in terms of overall frequencies, the results have been pooled. Table 3 shows that grafting under the kidney capsule gives a slightly higher proportion of beating compared to grafting in the ear, but the difference still exists between single and double grafts in two different strains. In fact the relative proportions of functional grafts for the two strains are in agreement by both methods of grafting and assessment (Tables 1 and 3). Grafting three hearts has no greater effect on an individual graft's functioning than grafting two hearts.

Since the adult heart does not interfere with single heart graft survival it is reasonable to enquire what effect an established heart graft would have on a second heart graft implantation. Therefore, we grafted single hearts in the left kidney capsule and 1 or 2 weeks later grafted a second heart in the right kidney capsule. The results of such a delay are shown in Table 4. The second graft seems to have no influence on the functioning of the first graft. The second graft, however, shows a significantly lower proportion of beating ($P < 0.05$). The proportion of second grafts functioning is higher than two hearts grafted at the same time, but not significantly different. This indicates that whatever is mediating this effect will not influence a graft that has been established for a week or two. An established

graft, however, can have some effect on a subsequent graft.

The data presented in this paper support the conclusion that the probability of an individual heart graft surviving in a syngeneic host is influenced by whether or not other hearts are grafted at the same time. This conclusion has been reached after examining a large number of grafts in two different strains and a smaller number in a third strain. There are a number of possible explanations for this observation. The first and most obvious one, that of observer bias, seems to be ruled out because the grafts were read blind using the electrocardiographic procedure. The results were extraordinarily consistent from one reading to the next. In other words, if a given animal had a positive left ear and negative right ear, this persisted from week to week during the period for which it was read, even though there was no way in which the reader could have known the previous results while the ears were being read. Also, at various stages three different people read the grafts and came to the same conclusion.

A second possible explanation could come from the additional time involved in grafting the second heart, which might compromise both grafts. In fact, the heart grafting can be done so rapidly with a little practice (approximately 30 s per ear) that this objection is highly unlikely. Furthermore, no adverse effect of grafting other foetal tissues into a contralateral ear was observed on single heart grafts.

Another explanation that needs to be considered is an immunological one. A segregating or foetal specific antigen might cause some of the heart grafts to be rejected. Three separate considerations render this explanation untenable. First of all, the difference between double and single heart grafts is apparent after 1 week (see Table 1). This would be too rapid for most types of graft rejection. Secondly, histological examination of nine electrocardiographically negative hearts removed 2 months after ear grafting revealed normal heart muscle tissue, indistinguishable from control positive grafts, and showing no sign of monocytic or polymorphonuclear infiltration. Finally, and most conclusively, the difference between double-grafted and single-grafted hearts persisted when the host animals were completely immunosuppressed. This was accomplished by irradiating CBA/J males with 650 R using a ¹³⁷Cs source

(Gamma Cell 40, Atomic Energy of Canada), a dose which completely suppressed the splenic plaque forming cell response to sheep red blood cells when immunised 24 h and assayed 5 d after irradiation. (Six unirradiated control immunised animals had a response of 8.41 (±3.91) × 10⁴ PFC per spleen. Six normal unimmunised mice had 153 (±190) PFC per spleen. Six mice given 650 R and immunised had 65 (±45) PFC per spleen.) The mice had heart grafts placed in their ears 24 h after irradiation and read electrocardiographically 7 d after grafting. Of the double grafts, 57% (8/14) were positive at one week, whereas 92% (11/12) of the single grafts were positive. This result closely resembles the data in Table 1 and indicates that complete immunosuppression of the host does not increase the percentage of functioning double heart grafts.

A more attractive explanation of these results might be the existence of a mechanism whereby a nascent heart sends out some signal to prevent another heart from developing along the same vascular tree. This could have obvious relevance for survival if the probability of more than one inductive signal for heart formation is appreciable. This speculation agrees with the experiment in which an established graft can influence the functioning of a graft put in subsequently, but the subsequent graft has no effect on the established graft. If some such mechanism exists and operates by a soluble factor it would not be possible for the factor to cross the placenta (at least in the maternal to foetal direction) because mice invariably have multiple offspring in the same litter. The reason for the existence of some doubly positive animals might be that the relatively large "space" of the adult host in the experimental situation (compared to the ordinary foetal "space") somewhat dilutes the effect.

Analogous observations have been made with grafted neonatal lymphoid organs. Metcalf showed that single neonatal spleen grafts placed subcutaneously into adult splenectomised mice grew much larger individually than did

Table 2 Specificity of double heart effect

Table 4 Effect of established graft on second graft

Fraction beating (total number) if second graft delayed for			
	1 week	2 weeks	Total
Established graft	1.00 (14)	0.93 (14)	0.96 (28)
Second graft	0.79 (14)	0.71 (14)	0.75 (28)

multiple grafts². In fact, the total spleen mass tended towards a constant value. Thus, six multiple grafts gave a total weight roughly equal to that observed with 12 multiple grafts. This effect was not observed when multiple spleen grafts were placed on the chorioallantoic membrane of chickens³. Metcalf found that neonatal thymus grafts, unlike spleen grafts, behaved autonomously, even though as many as 50 grafts were implanted subcutaneously, reaching a total weight of 800 g. Two different groups have reported nonetheless that the newborn offspring of neonatally-thymectomised females have enlarged thymuses compared to control litters born to sham-thymectomised females^{5,6}. The effect diminishes with subsequent pregnancies as the female herself becomes immunologically restored^{6,7}. It is not inconceivable, therefore, that a similar type of feedback mechanism operates during the development of the heart to prevent the disastrous consequences of two autonomous pumps operating on the same vascular tree.

Myelin deficit in the Jimpy mouse may be due to cellular abnormalities in astroglia

THE mouse mutant Jimpy is considered to be a model for certain human diseases in which the development of myelin is abnormal^{1,2}. Biochemical studies of Jimpy have shown that myelin components are reduced but no specific abnormality in the assembly of myelin has been detected²⁻⁴. This electron microscopic study describes for the first time abnormalities in astroglia of Jimpy optic nerve that are likely to inhibit the development of oligodendroglial cells and myelination.

Before the onset of oligodendrocyte formation in these mutants, processes of astrocytes begin to branch abnormally. The branching continues until most axons are surrounded by astrocytic processes. Such an arrangement would make it necessary for the oligodendrocytes to displace the glial processes in order to contact axons and make compact myelin. The cause of the astrocytic branching in Jimpy has not been proven but it may be related to the paucity of microtubules and profusion of 90-Å filaments found in astrocytes during the early stages of development. Microtubules are necessary for maintaining cell shape^{5,6}, so it is possible that their paucity and/or the filamentous hyperplasia is the underlying morphological defect responsible for the shape of astroglia in Jimpy.

Jimpy mice, obtained from breeding colonies sent by Jackson Laboratories, were studied at 2, 5, 10 and 23 d after birth. Optic nerves were examined at all stages and compared with spinal cords at 2 and 23 d after birth. Female hemizygotes were initially used as the only controls but

Fig. 1 Transverse sections of optic nerves from a 2-d postnatal Jimpy mouse (a) and a hemizygote (b). Both pictures are at the same magnification ($\times 150$) and they illustrate differences in the size of nuclei (large arrows) and the hypertrophy of astroglial processes (small arrows). The degree of the hypertrophy in Jimpy optic nerves is variable from animal to animal and even within the nerve. Note that the left side seems more affected than the right. The vacuoles are not artefacts of fixation but seem to be swollen, degenerating axons at the fine structural level.

these animals showed probable glial and axonal abnormalities at the fine structural level. Accordingly, homozygous normals and Swiss mice were also used.

During early postnatal development in the optic nerves of normal mice and rats, astrocytic processes divide the neurites into distinct fascicles⁷⁻⁹. These processes do not have many side branches but in Jimpy many fine branches penetrate into the axonal fascicles isolating neurites from each other (Fig. 2). This hyperplasia of astrocytic processes continues during myelinogenesis^{10,11} until the majority of axons are surrounded (Fig. 3).

In normal animals at 2 d after birth, the cytoplasm of astroglial cells contains an abundance of organelles including microtubules; the clusters of filaments characteristic of mature forms are less common⁷⁻⁹. In Jimpy mice at 2 d after birth, this relationship is reversed so that there is a paucity of microtubules and an abundance of filaments (Table 1). There is almost a fivefold difference in the number of microtubules in Jimpy when compared to Swiss

Fig. 2 Electron micrograph of the optic nerve from a 2-d-old Jimpy animal showing the branching of astrocytic processes (Ap) into fascicles of axons (A). The large, radially oriented processes give off numerous small branches which divide the axons into small compartments. Some of these processes have begun to separate individual axons from other axons (arrows). This extensive branching does not occur in normal animals (see references 7-9 for comparison illustrations). The radially oriented astroglial processes contain primarily 90-100-Å filaments but few microtubules (Table 1) ($\times 8,800$).

Table 1 Comparison of number of microtubules and filaments in astroglia of 2-d postnatal optic nerve

	Swiss strain	Hemizygote	Jimpy
No. of astrocyte microtubules per μm^2 of astrocyte cytoplasm	34.3	16.0	7.2
No. of astrocyte microtubules per μm^2 of optic nerve tissue	7.5	4.3	2.2
No. of astrocyte 90-Å filaments per μm^2 of astrocyte cytoplasm	~480*	~640	~1170
Ratio of astrocyte cytoplasm to optic nerve tissue	1:4.6	1:3.9	1:3.3

The number of longitudinally sectioned microtubules in astroglia was counted from electron micrographs printed at 13,000 and viewed with a Bausch and Lomb $\times 7$ magnifier. Ten to fifteen random pictures were used for each optic nerve; half of the pictures were taken from the centre of the nerve and the other half at the periphery. The area of the astrocyte cytoplasm was calculated with a Lasico planimeter. The area of optic nerve tissue included all cell nuclei and processes with the exception of vascular elements. The area of astrocyte cytoplasm surveyed ranged from 6.5 to 7.3 μm^2 . The quality of fixation for all animals was approximately the same.

* The precise number of 90-Å filaments is impossible to determine because the filaments overlap each other and weave in and out of the plane of the picture. The estimate for Jimpy is probably low because of the dense packing of filaments within a cluster.

mice and a twofold difference for the hemizygotes. It might be argued that the microtubule deficit is only an apparent one because the astrocytic cytoplasm is hypertrophied. But when the number of microtubules in astroglia is compared to the area of optic nerve (Table 1), there is still a two- to fourfold difference between Jimpy and the controls. The difference in the ratios between astrocytic cytoplasm and optic nerve area confirms the light and electron microscopic observations that there is a hypertrophy of astrocyte cytoplasm (Fig. 1). In contrast to the microtubule deficit, the number of 90-Å astroglial filaments is increased more than twofold (Table 1). Electron microscopic observations show that not only are the clusters of filaments more numerous but also that the filaments within the clusters are more densely packed. This observation correlates well with an immunofluorescent study¹² of astroglial fibrillary acidic protein in Jimpy mice. Although not commented on by these authors, the fluorescence for this substance is greater in Jimpy spinal cords than in the littermates used as controls (Fig. 1). This study shows that microtubule and filament abnormalities occur to a lesser degree in the hemizygotes.

While the astroglial cells in Jimpy optic nerve are strikingly abnormal in appearance, most of the oligodendroglia seem normal except that they are less differentiated than the controls. The number of oligodendroglial cells is, however, reduced more than 50% (Table 2). The percentage reduction of oligodendroglia depends, to some extent, on the interpretation of the unclassifiable cells. If all of the unclassifiable cells are considered to be oligodendroglia, there is a 48% reduction at 10 and 23 d after birth; if none is considered oligodendroglia, the loss is 61% and 79%. But approximately half of the unclassified cells at 10 and 23 d after birth seem to be oligodendrocytes and using this estimate, there is about a 53% and 62% reduction. An apparent reduction in the number of oligodendroglia in the corpus callosum has been noted^{13,14} but the severity of this deficit was not quantitated.

In previous studies of Jimpy nervous system, investigators have focused upon the period of myelin formation, and have primarily confined themselves to possible oligodendroglial and myelin abnormalities^{2-4,10,13-15}. The hyperplasia of astroglial processes described here for the optic nerve is, however, frequently noticeable in the published pictures (ref. 15, Figs 7 and 8). We show that these abnormalities are apparent at least a day before oligodendroglia are present and 3 or 4 d before myelination begins^{10,11}. This observation indicates that the astroglial hyperplasia is not triggered by the presence of oligodendrocytes.

The astroglial abnormalities raise the interesting question as to how they can affect the oligodendroglial cells. It is conceivable that the hyperplasia of astroglial processes, which occurs before and during myelinogenesis, could block the oligodendrocytic processes from reaching axons and forming proper internodes. However, it is more difficult to explain how the proliferation of oligodendrocytes can be

Fig. 3 Electron micrograph of a Jimpy optic nerve 23 d after birth. The astrocytic processes (Ap), most of which have been outlined, now surround the majority of axons (A). The glial processes are identified by the presence of numerous 90–100 Å filaments which appear as clusters of dots at this magnification. The profile of an oligodendrocyte (Ol) is identified by its electron dense cytoplasm and nucleus. The clumping of chromatin beneath the nuclear membrane is also a characteristic feature of this cell type. Three axons are surrounded by four to six turns of myelin lamellae ($\times 14,500$).

affected. Although the factors controlling oligodendroglial proliferation are unknown, the proliferation of the myelin-forming cells in the peripheral nervous system is stimulated by the presence of axons¹⁶. Perhaps the astroglial hyperplasia impedes contact between the axons and oligodendrocytes. Another possibility is that the normal number of oligodendroglial cells is generated but that some die shortly after cell division, due to lack of contact with axons. Thymidine autoradiographic studies should provide information about the proliferation kinetics of these cells. A third possibility is that the source of the oligodendrocytes might be affected. The origin of the oligodendroblast stem cell is

Table 2 Ultrastructural classification of different cell types present in a complete transverse section of optic nerve.

	Astroglia	Oligodendroglia	Microglia	Unclassifiable	Total cell no.
2-d postnatal Swiss mouse	54	0	0	19	73
2-d postnatal hemizygote	57	0	0	15	72
2-d postnatal Jimpy*	61	0	2	3	66
10-d postnatal homozygous normal	70	81	1	28	180
10-d postnatal Jimpy	75	32	1	25	133
23-d postnatal homozygous normal†	59	97	4	12	172
23-d postnatal Jimpy	60	20	8	37	125

The ultrastructural criteria for classification of differentiating glia in optic nerve is discussed in detail by Skoff *et al.*⁷ In the present study, two characteristic features of each cell type were required for a definitive classification (for example, filaments and electronluculent appearance for astrocytes). It is difficult to classify precisely all of the cells because some do not have sufficient characteristics for a positive identification or they have been sectioned through areas lacking cytoplasm. Complete transverse sections of the optic nerve were mounted on Formvar coated slot grids for electron microscopic examination. The cell counts were made directly from the viewing screen of an AEI-801 electron microscope. A scanning system was devised to avoid recounting the same cell; low magnification montages were made of two sections to check possible errors in counting. There was a 1 and 3% difference in the number of labelled cells using the scanning and montage methods. Only one animal was used for quantitation but at least two Jimpy animals were examined at each stage except at 23 d after birth when only one animal was available. The procedure for preparing optic nerve tissues for electron microscopy has been presented elsewhere⁷.

*2 d postnatal animals were identified as Jimpy on the basis of differences in the amount of myelin present in the spinal cord. At this time, axons in the ventral funiculus are beginning to myelinate and the spinal cords of Jimpy animals show fewer myelinated axons.

†The number of cells counted in a transverse section of a homozygous normal (172) compares favourably with a light microscopic cell count (162) by Friedrich¹⁸ of a (C57BL/6J) mouse.

uncertain but there are two likely sources⁷, a population of undifferentiated cells or the poorly differentiated astroblasts. The number of undifferentiated cells and poorly differentiated astroblasts is reduced in Jimpy optic nerve 2 d after birth, in comparison to controls.

Previous morphological and biochemical studies of Jimpy mice have shown that the scarcity of myelin is restricted to the central nervous system¹ and that the deficit is not due to a demyelinating disorder^{2,18}. Up to the present, however, no specific abnormality in the formation of myelin has been detected by biochemical studies²⁻⁴. The reduction in the number of oligodendrocytes described here is certainly one of the major factors responsible for the paucity of myelin in Jimpy but it does not elucidate the cause of the cellular reduction nor does it explain certain abnormalities in the appearance of the few myelinated fibres. The hyperplasia of astrocytic processes, which begins before the formation of oligodendroglia, could account for the myelin and oligodendroglial abnormalities. The hypothesis that astroglia affect oligodendrocytes is new but a precedent for such a cellular interaction in the developing central nervous system occurs between astrocytes and neurones in which the migrating neuroblasts fail to reach their destination in the absence of astroglial processes¹⁷. The effect of an overproduction of astrocytic processes on neuronal development has yet to be determined but the precocity of the "gliosis" in Jimpy, occurring when axons are still growing through the optic nerve, may be a model for studying the interactions between astroglia and axons in development.

Reversible loss of hippocampal long term potentiation following electroconvulsive seizures

ONE of the most intriguing electrophysiological phenomena observed in the central nervous system is the persistent enhancement of an evoked synaptic response following brief trains of electrical stimuli. Within the hippocampus, evoked synaptic potentials can be doubled or tripled by tetanising stimulation, and such changes persist for hours to weeks¹⁻⁶. Interest in the phenomenon of long term potentiation (LTP) stems from the generally held belief that synaptic plasticity of this sort may well be a physiological basis of information storage in the CNS. It is notable that this striking synaptic plasticity is observed in a structure which extensive clinical and experimental evidence suggests has a central role in information storage and/or retrieval⁷⁻¹¹. Included in this evidence are numerous demonstrations that disrupting hippocampal activity by electrically induced epileptiform seizures also disrupts memory formation and/or retrieval¹²⁻¹⁴. In addition, the effectiveness of a variety of other treatments in disrupting behavioural plasticity seems closely related to their ability to elicit convulsive activity in the hippocampus^{15,17}. We report here a series of experiments indicating that LTP established in the hippocampus can also be reversibly disrupted by the same kind of convulsive activity which disrupts memory functions. Specifically, we have produced LTP in the CA1 pyramidal cell synaptic field, disrupted it with electrically induced hippocampal seizures, and subsequently reinstated it with low frequency tetanic stimulation.

Adult Lashley rats were given atropine sulphate (intramuscularly, 0.2 mg kg⁻¹) and anaesthetised with an intraperitoneal injection of allobarbitol (60 mg kg⁻¹) and urethane (240 mg kg⁻¹). The hippocampus was exposed by aspirating the overlying cortex, and was continuously bathed in warm (37-38 °C) mineral oil. Electrodes were placed to stimulate fibres within the stratum radiatum of the CA3 field and to record the extracellular population excitatory postsynaptic potential (e.p.s.p.) from stratum radiatum of the CA1 field. An additional electrode, well removed from the other two, was used to generate electroconvulsive

seizures in the hippocampus. In most cases an input-output function was first obtained by recording the CA1 synaptic response to CA3 stimulation over a range of stimulus intensities. Subsequently, several low frequency trains of impulses (12 Hz for 15 s, 8 min inter-train interval) were delivered while monitoring the CA1 synaptic response with a probe stimulus continually applied at 0.2 Hz.

The low frequency tetanic (LFT) stimulation produced long term increases in the evoked population e.p.s.p. amplitude ranging up to about 300% (mean 175.8%), along with decreases in the stimulus intensity required to elicit a population spike from the CA1 pyramidal cells. The effects of LFT stimulation were cumulative, and maximum potentiation was usually obtained after three to six LFT trains. That the potentiation was truly long term was established in several experiments where it persisted with little or no decline for periods of over an hour (the duration of the experiment) following the last LFT.

In 18 experiments hippocampal seizures were induced at various intervals following a series of LFT trains. Seizures were evidenced by afterdischarges lasting up to 45 s, followed by complete post-ictal depression of the response for up to 10 min, then a period of gradual response recovery. Recovery was considered complete when the response showed no further change for 10 min. The overall recovery periods ranged from 15 to 25 min following the seizure.

The effect of these induced seizures was dramatic (Fig. 1). In all 18 experiments the LTP established by repeated tetanic stimulation was wholly or partially abolished. In none of these experiments did the post-seizure response recover to the potentiated response level, and in all but two cases the post-seizure response recovered to at least the level of the initial unpotentiated control response. In both of these cases a sudden drop in the response during the re-

covery period suggested probable electrode movement. The magnitude of the drop was approximately equal to the difference between the final recovery and initial control responses. Excluding these two experiments, the effect of the seizures was to reduce the LFT-induced response potentiation by a mean 83.5% (the mean post-recovery response was 119.8% of the initial control response).

The interference with LTP produced by the seizure seemed partially or wholly reversible. In ten experiments additional LFT trains were administered after a seizure had wholly or partially eliminated the LTP established by the initial LFT stimulation. In eight of these experiments LTP was re-established, and such plasticity was evident through as many as four cycles of the LFT-seizure-recovery procedure (Fig. 2).

As is evident in both Figs 1 and 2 there was, in general, a progressive decrease in the amount of LTP which could be realised following successive seizures. In those experiments in which LFT was administered after a seizure, the second LFT series produced only about half (45.2%) as much plasticity as the pre-seizure stimulation produced. Comparable decreases in plasticity seemed to be the rule following a second or third seizure. It is not clear whether the decreasing potential for plasticity represents a real limitation of the processes involved or is simply a "tired tissue" phenomenon. The latter possibility seems probable, since it is noted that less electrophysiological plasticity of any type is evident in longer experiments³.

These results might be interpreted as being due to an inadequate period of recovery following the seizure. To test this possibility, post-seizure responses were monitored in several experiments for 20–50 min after stabilisation rather than the usual 10 min (Fig. 2c). Despite this, no additional recovery was noted. Hence, these results cannot

Fig. 1 CA1 extracellular population e.p.s.p. response magnitude to test stimuli during the establishment of long term potentiation (circled points), its interruption by electrically induced electroconvulsive seizure (arrows), and recovery from seizure related post-ictal depression (following the dashed lines) in a typical experiment. The circled points are test responses immediately preceding low frequency tetanic stimulation (12 Hz for 15 s). The low frequency tetanic stimulation resulted in increases in synaptic efficacy which were abolished by the seizure. Following recovery from post-ictal depression, additional tetani again resulted in a potentiated response, but of progressively lower magnitude. Raw records are shown corresponding to the indicated points on the graph. CA1: 1 mV, 5 ms. Control (0.2 Hz, 0.1 ms duration, 5–20 V) and tetanic (12 Hz, 0.1 ms duration, 5–20 V) stimulus pulses were delivered through an insulated monopolar stainless steel electrode (20–40 μ m exposed tip) placed in stratum radiatum of CA3 to activate axons (primarily Schaffer collaterals) projecting to CA1. A similar monopolar recording electrode was placed in stratum radiatum of CA1 (about 4 mm posterior to the stimulating electrode) to record the CA1 extracellular population e.p.s.p. A similar monopolar stimulating electrode was placed 1 mm deep posterior and lateral to the recording site. Seizures were induced through this electrode by a 1-s train of 60 Hz, 15 V pulses (biphasic, 1 ms duration, roughly 300–400 μ A).

Fig. 2 Six experiments (a-f) in which a number of variables were manipulated relative to seizure disruption of long term potentiation. Circled points are extracellular population e.p.s.p. magnitudes plotted relative to a pre-tetanus control (= 100). The numbers refer to the number of tetanic stimulations delivered; the following point is the stimulation induced potentiation. Electrically-induced or spontaneous (sp) seizures are indicated by arrows. The first seizure occurs at time zero (except for d). Note that the seizure interferes with long term potentiation regardless of the number of tetani, time after initial potentiation, or means of inducing seizures. Additional tetani result in repotentiation.

be readily attributed to inadequate recovery from seizure.

Another alternative explanation for these results is that the electroconvulsive stimulation and seizures produced a generalised decrease in the excitability of the hippocampus. That this was not the case is evidenced by several types of data. Seizure and recovery prior to LFT stimulation did not alter the response to the probe stimulus, nor did this preclude subsequent establishment of LTP. In some experiments where no LTP was observed, a seizure was nevertheless induced following several ineffective LFT trains. In these cases the post-recovery response was virtually unchanged from the pre-seizure level. In addition, in only two experiments (those noted earlier) was the threshold stimulation required to elicit a population e.p.s.p. appreciably different following seizure recovery than the threshold before the seizure, and before the LFT stimulation¹⁴. It should also be noted that in most cases pre-seizure LFT stimulation was continued until no further response increases were observed, and the response was "fully potentiated." In spite of this, additional plasticity was evident following a seizure. Finally, in three cases "spontaneous" seizures occurred during an experiment with the same result as electrically-induced seizures—total or partial elimination of LTP (Fig. 2a, e).

The data presented here indicate that electroconvulsive seizures induced in the hippocampus interfere with the processes underlying long term potentiation of evoked synaptic responses, and that this interference is at least partially, and perhaps wholly, reversible. Thus, hippocampal seizures seem to have quite analogous effects on both behavioural and electrophysiological plasticity. The evidence presented

here does not allow a decision on the relative importance of the convulsive activity *per se* against that of the post-ictal spreading depression (SD) in producing these effects. However, preliminary observations of a similar effect following topical application of KCl suggest that SD is the essential correlate of LTP interference.

We cannot comment conclusively on mechanisms which might mediate the effects described here, since the mechanisms underlying LTP are as yet unclear. Nor do we know if processes similar to these occur as a normal concomitant of hippocampal functioning. But our results seem consistent with one proposed mechanism of LTP. Van Harreveld and Fikova¹⁸ have proposed that LTP is the result of stimulation-induced swelling, and consequent conduction increase, of dendritic spines. Anatomical evidence seems to support their assertion, and there is limited evidence of the possible behavioural relevance of this mechanism^{19,20}. It is also notable that SD is accompanied by dendritic and somatic swelling, presumably mediated by the same mechanism responsible for stimulation-induced spine swelling, though in a more extreme manifestation. Since SD swelling is clearly reversible²¹, it is plausible to suggest that the extensive SD induced by seizures in our experiments triggered recovery processes which reversed not only dendritic and somatic swelling, but the presumed LFT-induced spine swelling as well. Thus, recovery from a seizure would be accompanied by a reduction or elimination of any LTP existing prior to the seizure, but would not preclude the re-establishment of LTP by further stimulation. Though this is clearly only a tentative hypothesis, it is consistent with the available data, and it does suggest additional experiments which could decide these issues.

Evidence for dopamine receptors mediating sedation in the mouse brain

APOMORPHINE, a direct stimulant of dopamine (DA) receptors, and L-dopa, the direct precursor of DA, have a biphasic action on behaviour, in low doses they decrease motor activity, while in higher doses they cause hypermotility and stereotypy¹⁻³.

While the stimulant effect is considered to be due to the activation of postsynaptic DA receptors in brain^{4,5}, it has been suggested that the depressant response to these drugs is due to the activation of DA "autoreceptors", which would

result in inhibition of DA synthesis and dopaminergic firing^{3,6,7}.

However, while there is experimental evidence that the inhibition of DA synthesis and neuronal firing, which is blocked by neuroleptics, is due to stimulation of DA receptors^{8,9}, no such evidence exists for the sedative effect. Moreover the idea that the sedative effect of apomorphine depends on decreased dopaminergic activity is simply based on the observation that the two events are correlated in dose-response studies².

The demonstration that the sedative response to apomorphine and L-dopa is due to stimulation of DA autoreceptors is hampered by the fact that neuroleptics, which are antagonists at CNS DA receptors, themselves cause sedation.

We considered that some neuroleptic compounds might be found with higher affinity for auto- than for postsynaptic receptors and that such compounds might thus demonstrate the DA-mimetic nature of the sedative effect of DA receptor agonists.

We report here that some neuroleptics, at doses lower than those producing sedation, are capable of preventing the sedative effect of apomorphine and L-dopa in mice. At these doses these compounds are also effective in preventing the apomorphine-induced decrease in DA synthesis, as reflected by brain DA metabolite levels.

Figure 1 shows the effect of 0.1 mg kg⁻¹ of subcutaneous apomorphine in control mice and in mice pretreated with pimozide at the non-sedative dose of 0.3 mg kg⁻¹, 20 min previously.

Apomorphine decreased motor activity, and this effect

Fig. 1 Effect of pimozide on the hypomotility produced by apomorphine in mice. Mice were pretreated with pimozide (0.3 mg kg⁻¹ intraperitoneally) 20 min before apomorphine (0.1 mg kg⁻¹ subcutaneously). Ten min after apomorphine the animals were placed for the first time in the motility cage (Motron, Sweden) and motility was measured immediately. In these conditions, this generally took the form of exploratory activity. At the dose used in this experiment, apomorphine dramatically reduced the activity such that after the first 10 min, while control mice were still highly active, mice treated with apomorphine lay down in a corner and appeared sedated. The schedule used for pimozide was the most effective in preventing the sedation produced by apomorphine without producing sedation *per se*. Use of longer time intervals (3 h) for pretreatment with the 0.3 mg kg⁻¹ dose of pimozide results in sedation. However, similar antagonism of apomorphine hypomotility, even if less dramatic, was obtained after a 3-h pretreatment with 0.1 mg kg⁻¹ of pimozide. The results are the mean of four experiments. Open symbols indicate a significant difference ($P < 0.01$) between the curves with the same symbols as evaluated by non-parametric multivariate analysis¹⁰. ■, apomorphine; □, pimozide and apomorphine; ○, pimozide; ●, control.

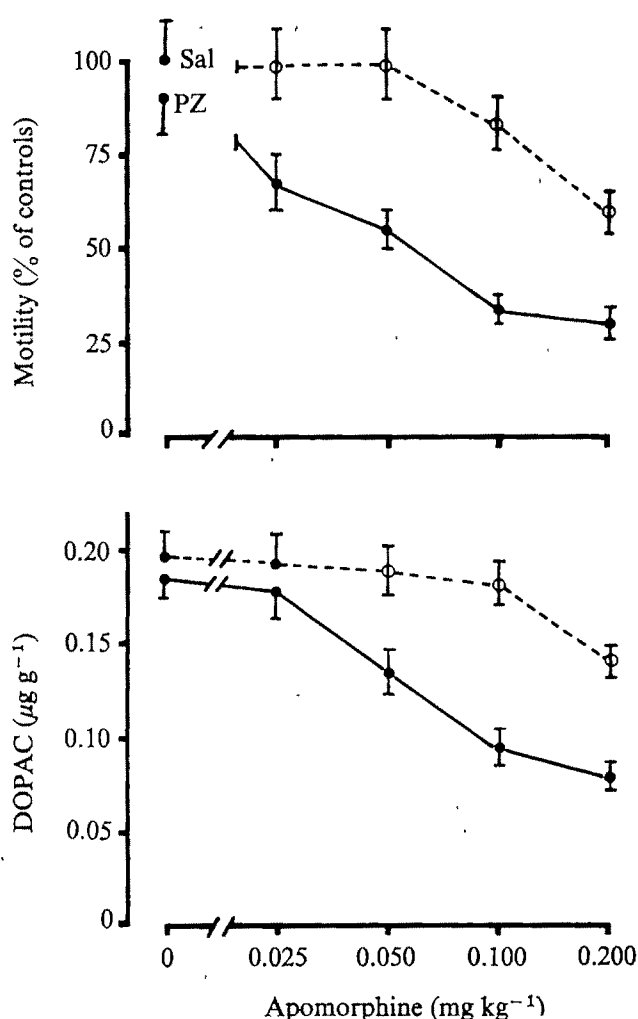

Fig. 2 Antagonism by pimozide of the hypomotility and decrease of brain DOPAC produced by apomorphine in mice. Pimozide (0.3 mg kg⁻¹ intraperitoneally) was administered 20 min before apomorphine. Apomorphine was administered subcutaneously and 10 min later the animals (4 cage) were placed in the motility meters (Motron, Sweden), and motility counted for 20 min. Mice were killed at the end of the motility test and DOPAC assayed fluorometrically according to Di Chiara *et al.* (unpublished). The effect of pimozide on apomorphine hypomotility was calculated as % of the motility obtained after pimozide alone. The results are the mean \pm s.e.m. of 4 experiments. Open circles indicate a significant difference ($P < 0.01$) with respect to apomorphine alone. ●, apomorphine; ○, pimozide and apomorphine.

was prevented by pimozide; the latter also prevented apomorphine-induced decrease of brain 3,4-dihydroxyphenyl acetic acid (DOPAC), the deaminated metabolite of DA.

Figure 2 shows the effect of increasing doses of apomorphine on the motor activity and brain DOPAC of control mice and of mice pretreated with pimozide, 0.3 mg kg⁻¹, given 20 min earlier. Apomorphine caused a dose-dependent decrease in motor activity and of DOPAC levels both in control and in pimozide-treated mice. However, pimozide, which *per se* did not significantly influence motor activity or brain DOPAC, shifted to the right the dose-response curve of apomorphine-induced hypomotility and brain DOPAC decrease, suggestive of competitive antagonism.

The antagonism exerted by pimozide on the effects of apomorphine was not related to a modification of the tissue distribution of apomorphine, since pimozide did not modify the time-course of the levels of ³H-apomorphine in brain (results not shown).

Similar results were obtained with other neuroleptics such as haloperidol, benzperidol, droperidol and sulpiride: as shown in Table 1, these compounds, at doses which did not

influence motor activity or brain DOPAC, prevented both the hypomotility and the fall in brain DOPAC produced by apomorphine.

On the contrary, clozapine and trifluoperidol, at non-sedative doses, failed to influence either the sedative or the biochemical effects of apomorphine.

Neuroleptics active against the inhibitory effects of apomorphine were also able to prevent the sedative effect of L-dopa, when administered at a schedule similar to that used against apomorphine. As Fig. 3 shows, sulpiride shifted to the right the dose-response curve of L-dopa-induced hypomotility, again suggesting a competitive-type antagonism, as for pimoizide against apomorphine.

In the above conditions, sulpiride did not influence the amount of DA formed in brain after L-dopa administration.

The present results show that different neuroleptics, such as haloperidol, droperidol, pimoizide, benzperidol and sulpiride are able to prevent the sedative effect of apomorphine and L-dopa and also the ability of apomorphine to inhibit the activity of the DA system, as estimated by the decrease in brain DOPAC^{8,10}. Since neuroleptics are specific and competitive antagonists of the DA receptors both *in vivo* and *in vitro*¹¹⁻¹³, the present results strongly indicate that apomorphine and L-dopa produce sedation and decrease dopaminergic activity by stimulating central DA receptors, as suggested by Carlsson and by Strömbom^{2,3}. Moreover, the strict correlation between the behavioural and biochemical changes indicate that the sedative effect of apomorphine depends on the decreased DA activity.

As to the nature of the DA receptors mediating the inhibitory effects of L-dopa and apomorphine, they should be considered quite distinct from the inhibitory receptors

Table 1 Effect of various neuroleptics on the hypomotility and brain DOPAC decrease produced by apomorphine

Neuroleptic	Dose (mg kg ⁻¹)	Motility (% of control)	DOPAC (μg g ⁻¹)
Control	—	100 ± 11	0.185 ± 0.008
None	—	25 ± 3.2	0.095 ± 0.006
Benzperidol	0.050	85 ± 9.5	0.180 ± 0.010
Droperidol	0.050	80 ± 7.5	0.178 ± 0.009
Haloperidol	0.050	75 ± 8.5	0.175 ± 0.008
Pimoizide	0.300	83 ± 9.3	0.182 ± 0.009
Sulpiride	10.0	87 ± 8.5	0.192 ± 0.010
Trifluoperidol	0.050	27 ± 3.0	0.098 ± 0.007
Clozapine	0.50	23 ± 2.5	0.097 ± 0.006

All neuroleptics were administered intraperitoneally 20 min before apomorphine (0.1 mg kg⁻¹ subcutaneously); mice were placed in the motility cages (4 mice per cage) 10 min after apomorphine administration and motility counted for 20 min. At the end of the motility test, the animals were killed and DOPAC assayed fluorimetrically according to Di Chiara *et al.* (in preparation). The dose of neuroleptic reported in the table is the lowest non-sedative one which was found experimentally to be maximally effective in antagonising apomorphine hypomotility. In the case of trifluoperidol and clozapine, for which antagonism could not be shown, the dose reported is the highest non-sedative one. At the dose reported, neuroleptics alone did not modify significantly the control levels of brain DOPAC nor the motility. Nonetheless, the effect of neuroleptics on apomorphine hypomotility was always calculated as % of the motility obtained when the neuroleptics were administered alone.

Each value is the mean ± s.e.m. of 4 experiments. All neuroleptics, except trifluoperidol and clozapine, significantly ($P < 0.01$) modified motility and brain DOPAC with respect to apomorphine alone.

postulated by Cools *et al.*¹⁴, which are not stimulated by apomorphine and are not blocked by neuroleptics. Our results support the concept of regulatory DA receptors by which the DA system controls its own activity (autoreceptors)³. The exact location of these receptors is not clear. They might be prejunctional, that is, located on the membrane of the DA neurone itself and stimulated by an overflow of the transmitter¹⁵, or in the substantia nigra, where a postsynaptic DA-sensitive adenylate cyclase^{16,17} and a vesicular release of DA from dendrites have been shown¹⁸.

The results reported here indicate the possibility of influencing behaviour by acting with drugs on a special type of DA receptor; this might constitute the basis for the development of more potent and selective blockers of DA autoreceptors and might provide an entirely new means of controlling the activity of the DA system.

We thank Professor Piero Fresia, "Ravizza S.p.A.", Muggiò (Milano) for supplying sulpiride.

β -Endorphin *in vitro* inhibition of striatal dopamine release

THERE has been considerable recent interest in endogenous peptides as possible analgesic agents since the isolation of a pentapeptide with opiate-like activity (methionine-enkephalin) from porcine brain¹. Of particular interest is β -endorphin, isolated from camel pituitary glands², and now synthesised³. We report here the inhibitory effect *in vitro* of β -endorphin on striatal dopamine release from the central nervous system (CNS).

β -Endorphin consists of 31 amino acid residues with a sequence identical to amino acid residues 61-91 in the 91 amino acid peptide of ovine β -lipotropin^{4,5}. The first five amino acids of β -endorphin (residues 61-65 in β -lipotropin) are identical with methionine-enkephalin (Met⁵-enkephalin)¹ and were found to possess opiate activity in receptor binding assays and in electrically stimulated preparations of mouse vas deferens and guinea pig ileum. Subsequent studies have shown that β -endorphin also possesses opiate activity in receptor binding assays and in guinea pig ileum^{6,7}. More recently, it has been found that β -endorphin, in contrast to Met⁵-enkephalin, has potent analgesic properties when administered directly into the brain and assessed in the tail-flick, hotplate, and writhing tests in mice and in the wet shake test in rats⁸. In these tests, β -endorphin was found to be 18-33 times as potent as morphine on a molar basis and its actions were inhibited by the opiate antagonist naloxone. Although also antagonised by naloxone, Met⁵-enkephalin is an extremely weak and short-acting analgesic peptide⁹. In addition, β -endorphin was shown to be 3-4 times more potent than morphine when injected intravenously¹⁰.

The purpose of this study was to compare the abilities of morphine, β -endorphin and Met⁵-enkephalin to inhibit the

Fig. 1 Concentration-dependent inhibition of potassium-stimulated tritium overflow by β -endorphin. Concentrations of β -endorphin are indicated as follows: 0 μ M (●—●); 0.6 μ M (□—□); 1.2 μ M (■—■); and 3.0 μ M (○—○). Male Sprague-Dawley rats (200-350 g) were administered the monoamine oxidase inhibitor nialamide (100 mg kg⁻¹ intraperitoneally) 1 h before they were killed. Striatal tissue was dissected from a coronal slice of rat brain (1.5 mm thick) and incubated at 37°C in oxygenated (95% O₂, 5% CO₂) Krebs-Ringer bicarbonate (KRB) buffer (pH 7.4) containing ascorbic acid and 10⁻⁷ M ³H-dopamine, for 20 min. The slices were washed with warm buffer and placed into 13-mm Swinex Millipore filter holders (1 slice/holder) for superfusion by a 4-channel peristaltic pump. The perfusion rate was 0.5 ml min⁻¹ and 2-ml fractions were collected directly into scintillation vials for counting the tritium. Slices were superfused for 20 min and then superfused with β -endorphin for 20 min before switching to KRB containing 53 mM KCl + β -endorphin (indicated by the horizontal bar), the extra KCl having replaced some of the NaCl in the regular KRB. During the collection of fraction 15, the perfusing solution was switched back to regular KRB. Tritium overflow is expressed as a percentage of the mean of 4 experiments. Preliminary studies with alumina absorption chromatography indicated that approximately 82% of the tritium in regular KRB perfusates was dopamine and this value increased to about 93% in 53 mM KCl KRB perfusates.

Table 1 Opiate inhibition of striatal tritium overflow and reversal by naloxone

Drug	Concentration	Net overflow (%)
Morphine	0	17.69 ± 2.69 (13)
Morphine	1.0 × 10 ⁻⁴ M	16.14 ± 3.42 (8)
Morphine	3.0 × 10 ⁻⁶ M	5.04 ± 1.17* (10)
Morphine	1.0 × 10 ⁻⁶ M	0.41 ± 0.25* (5)
Morphine + Naloxone	3.0 × 10 ⁻⁶ M α	16.85 ± 3.02 (8)
β -Endorphin	0	20.04 ± 2.99 (4)
β -Endorphin	0.6 × 10 ⁻⁴ M	16.76 ± 3.62 (4)
β -Endorphin	1.2 × 10 ⁻⁶ M	8.06 ± 1.60* (4)
β -Endorphin	3.0 × 10 ⁻⁶ M	0.12 ± 0.12* (4)
β -Endorphin + Naloxone	3.0 × 10 ⁻⁶ M α	10.70 ± 2.72† (4)
Enkephalin	0	18.09 ± 2.44 (7)
Enkephalin	1.0 × 10 ⁻⁶ M	20.99 ± 4.70 (8)
Enkephalin	1.0 × 10 ⁻⁴ M	17.23 ± 4.11 (5)

*Significantly different from control ($P < 0.02$)

†Significantly different from 3 × 10⁻⁶ M β -endorphin alone ($P < 0.01$).

Rat brain striatal slices were used as described in the legend to Fig. 1. Net overflow was calculated from tritium in fractions 11-15 corrected for the estimated spontaneous tritium overflow and is expressed as a percentage (mean ± s.e.) of the total tritium in the striatal slice at the beginning of the collection of fraction 11. Numbers in parentheses indicate the number of experiments.

potassium-stimulated overflow of tritium from superfused rat brain striatal slices preloaded with ³H-dopamine. Recent studies from our laboratory have shown that potassium-induced ³H-dopamine release from superfused striatal tissue from several strains of mouse which exhibit running activity in response to morphine can be inhibited by 10⁻⁴ M morphine^{11,12}. This inhibition of release seems to be a specific opiate effect because it is antagonised by naloxone, and striatal tissue from mice made tolerant to morphine by the implantation of a morphine pellet for 3 d exhibits tolerance to the inhibitory effect of morphine on dopamine release *in vitro*¹³.

Figure 1 shows the concentration-dependent inhibition of the potassium-stimulated overflow of tritium by β -endorphin from superfused rat striatal slices. Virtually complete inhibition was obtained with 3.0 μ M β -endorphin. In Table 1, the effects of morphine, β -endorphin and Met⁵-enkephalin on the net tritium overflow induced by the depolarising concentration of potassium chloride are compared. β -Endorphin was about twice as potent as morphine, the IC₅₀ for β -endorphin being 1.0 μ M and the IC₅₀ for morphine being 2.2 μ M. Met⁵-enkephalin, on the other hand,

did not produce a significant blockade of the inhibition by morphine and β -endorphin, the blockade being more complete in the presence of morphine than in the presence of β -endorphin.

In the electrically-stimulated guinea pig ileum, Met⁵-enkephalin is approximately equipotent with normorphine¹ or morphine¹², whereas in the mouse vas deferens it is about 20 times as potent as normorphine¹ or morphine¹². β -endorphin and Met⁵-enkephalin are approximately equipotent in the guinea pig ileum preparation⁶. In opiate receptor binding assays with guinea pig brain membranes, Cox *et al.*⁶ have shown that synthetic β -endorphin is 2–3 times as potent and Met⁵-enkephalin one-fifth as potent as normorphine. Thus, the order of potency of β -endorphin, morphine and Met⁵-enkephalin in the inhibition of striatal dopamine release seems to follow more closely the order in the binding and analgesia assays than in the assays utilising smooth muscle preparations.

In a very recent paper, Taube *et al.*¹⁴ have described inhibition of noradrenaline release by enkephalin in rat cortex slices. However, to our knowledge, this is the first demonstration of an inhibition of dopamine release from CNS tissue by an endogenous opiate-like peptide. The actions of β -endorphin in the central nervous system are probably not limited to the inhibition of dopamine release because it is known that opiate drugs also inhibit the release of acetylcholine^{15–18} and noradrenaline¹⁹ from CNS tissue. At present, however, dopamine is the only neurotransmitter for which tolerance to the effect of morphine *in vitro* has been demonstrated with CNS tissue¹¹ and for which an inhibition of release by morphine has been correlated, at least qualitatively, with a behavioural effect of morphine, by utilising mouse strain differences^{11,12}.

We thank Dr E. T. Iwamoto for the alumina chromatography of the superfusates. This work was supported in part by grants from the NIDA and NIH. D. A. B. is a recipient of a USPHS postdoctoral fellowship.

Immunochemical evidence of cholecystokinin-like peptides in brain

A NUMBER of peptides including substance P¹, somatostatin² and vasoactive intestinal peptide³, have been found both in nerve cells of the brain and gut and in gastrointestinal endocrine-like cells. The biological significance of the occurrence of the same peptides in endocrine and nerve cells is not yet clear, although Pearse has suggested that these cell types might share a common embryological (neuroectodermal) origin⁴. An antibody to the antral hormone gastrin has recently been shown to cross react with material in extracts of the central nervous system (particularly cerebral hemispheres) of a number of vertebrate species including dog and man⁵. It is known that in antral mucosa, and in blood, gastrin occurs in several different forms of which the most important are peptides of 17 (G17) and 34 (G34) amino acid residues⁷. The C-terminal heptadecapeptide of G34 is identical with G17, and G34 may well be a biosynthetic precursor of G17 (ref. 7). The C-terminal pentapeptide of the two gastrins is also identical with that of the intestinal hormone cholecystokinin (CCK)⁸, and antibodies specific for the C terminus of gastrin frequently cross react with CCK⁹. The present study was undertaken to clarify the relationships between the gastrin-like activity in brain and the characteristic forms of gastrin and CCK. We found the distribution of the brain components on Sephadex G-25 to differ from those of previously characterised forms of gastrin and CCK. The pattern of reactivity with different antisera suggests, however, that the brain factors resembled CCK-like peptides more closely than gastrin-like peptides.

Extracts were prepared from the entire brain of rats, and from the cerebral cortex of hog and dog. Small pieces of tissue were boiled in water (0.5 g ml⁻¹) for 3 min to inactivate enzymes, homogenised, centrifuged (2,000g, 20 min) and the supernatant fractionated on calibrated columns of Sephadex G-25 or G-50. Immunoreactivity in the column eluates was estimated by radioimmunoassay using a C-terminal-specific antiserum (1296) (ref. 10).

Three peaks of immunoreactive material were found in column eluates when extracts of hog brain were fractionated on Sephadex G-25 (Fig. 1); similar results were obtained with extracts of rat and dog brain. The first peak (BP I) emerged in the void volume and accounted for 10–15% of the total immunoreactivity. Standard samples of G34 and CCK also emerged in the void volume on Sephadex G-25. But BP I differed from these standards in that it also emerged in the void volume after refractionation on Sephadex G-50, whereas G34 and CCK emerged later on Sephadex G-50 (approximately 35% and 50% respectively of total elution volume). In extracts of jejunum, and in plasma, there is material with gastrin-like immunoreactivity which emerges in the void volume on Sephadex G-50, and this component has been named 'big, big gastrin' (BBG) (ref. 11). Trypsin converts BBG to a peptide resembling G17 (ref. 11). In contrast, preliminary experiments indicated that when BP I was digested with trypsin (100 μ g ml⁻¹, 10 min) there was conversion to material emerging later than G17 on Sephadex G-25, at 60–90% of elution volume. So far only relatively small amounts of this product have been available and the identity of the material is not yet clear. Nevertheless the evidence indicates that BP I does not correspond to any of the previously characterised forms of gastrin or CCK.

The main peak of immunoreactivity in the brain extracts (BP II) eluted from Sephadex G-25 in a similar position to the C-terminal octapeptide of CCK (CCK 8); this peak accounts for over 70% of the total immunoreactivity (Fig. 1). A third peak of activity (BP III) representing 10–15%

Fig. 1 Fractionation of an extract of hog brain on Sephadex G25 superfine (1×100 cm). Fractions of 1.0 ml collected every 10 min. Column eluted with 0.02 M sodium barbital pH 8.4, containing 0.02% sodium azide, at 4°C . The column was previously calibrated with 20% pure porcine CCK, pure natural human G34-I and G17-I, caerulein, synthetic peptides corresponding to the C-terminal tridecapeptide (G13) and octapeptide of G17-I (G8), and CCK 8. The elution volumes of the standards are indicated by arrows. In all column runs the void volume was marked by protein estimated by absorption at 280 nm, and the salt region was marked by Na^{125}I . Elution volume is expressed as percentage from void (0%) to ^{125}I (100%). Concentration of immunoreactive material was estimated with antiserum 1296 and expressed relative to standard G17. Peaks of immunoreactivity are identified by Roman numerals.

of the total immunoreactivity emerged considerably later than Na^{125}I (Fig. 1). Synthetic peptides corresponding to the C-terminal hexapeptide and tetrapeptide of G17 were found to emerge in the same region as BP III, but the standards were poorly resolved and it has not been possible to relate precisely their mobility to that of BP III.

The immunochemical properties of the components in brain were studied by separately pooling fractions corresponding to the three peaks and estimating concentrations of immunoreactive material by radioimmunoassay using six different antisera. The specificities of the antisera had been established by studies of the potency of standard molecular forms and synthetic fragments of gastrin and CCK in inhibiting binding of ^{125}I -labelled G17 to antiserum. Only antisera specific for the C terminus of gastrin and CCK cross reacted with the brain components. Antiserum L6, which has specificity for intact G17 (ref. 12), and antiserum 1295, which is specific for the N terminus of G17 (ref. 10), failed to cross react with extracts of the brain of rat, dog or hog, either before or after fractionation by gel filtration (Table 1). Neither 1295 nor L6 cross reacted with rat antral

gastrin so their inability to detect immunoreactive material in rat brain is not surprising. Both antisera did, however, cross react with dog and hog G17 and so the failure to detect activity in brain extracts from these species indicates that G17 could be present only in minute quantities, if at all, in the extracts. These results are therefore consistent with the failure to find a peak of immunoreactive material eluting in the same region as standard G17 when brain extracts were fractionated on Sephadex G25 (Fig. 1).

When G17 was used as a standard in the radioimmunoassays there were up to 100-fold differences in concentrations of brain components estimated with different antisera (Table 1). For each of the components the highest concentrations were recorded with antiserum C. This antiserum was raised against CCK 8 and shows twofold higher immunoreactivity with CCK 8 than with G17. On the other hand the lowest values were recorded with antiserum L2, which was raised against porcine G17 and shows 50–100 times higher immunoreactivity with G17 than with CCK 8. Two other antisera (1296, 2716) gave intermediate estimates of the concentration of brain components; both of these antisera were raised against human G17 and show 5–15 times higher immunoreactivity with G17 than with CCK 8.

Because the pattern of immunoreactivity of the brain extracts seemed to follow the degree of specificity of the antisera for CCK, the results have also been expressed relative to a CCK standard. Pure CCK was not available and so CCK 8, which contains the minimal active fragment of CCK for biological activity, was used instead. Table 1 shows that there were only relatively minor differences in estimates of immunoreactive concentration of brain components made with different antisera when based on the CCK standard. The differences between antisera were more pronounced for BP I (two- to six-fold) than for BP II and III (one- to three-fold). Taken together the results indicate that the brain components have a pattern of immunoreactivity resembling CCK-like peptides more closely than gastrin-like peptides.

An attempt to isolate these brain peptides has been initiated in this laboratory; until this is achieved absolute estimates of their concentration in brain cannot be made. Expressed in terms of CCK 8 equivalent, however, the main component (BP II) was present in amounts of $50\text{--}150\text{ pmol g}^{-1}$ in the brain of the three species (Table 2). It is unlikely that concentrations such as these could be produced other than by synthesis within the CNS. Many peptide hormones are synthesised in the form of large precursor molecules which are converted to smaller biologically active forms by proteolytic enzymes. The present results could therefore be accounted for if the three components were the product of a single biosynthetic pathway and interconversion took place by proteolysis. It is clear that the cellular origins of these components must now be studied. In addition, attention must be given to the biological activity of

Table 1 Concentration of three fractions of hog brain estimated by radioimmunoassay with six antisera

Fraction	Standard	Antiserum				1295	L6
		C	2716	1296	L2 Concentration (pmol l^{-1})		
Hog BP I	G17	156	34	34	8	<2	<2
	CCK 8	78	100	212	472	—	—
Hog BP II	G17	2,341	177	119	23	4	2
	CCK 8	1,170	520	735	1,355	—	—
Hog BP III	G17	130	14	13	1	<2	<2
	CCK 8	65	41	81	58	—	—

Each figure is the mean of assays on three separate samples of brain extracts. Samples were pooled from eluates of Sephadex G25 columns. Results are expressed relative to standard pure natural human G17-I and synthetic C-terminal octapeptide of CCK (CCK 8). ^{125}I -labelled human G17 was used as label in all radioimmunoassays. With all four C-terminal specific antisera (C, 2716, 1296, L2) dilution curves for the three brain components were parallel to those for G17 and CCK 8. Antisera 1295 and L6 do not cross react significantly with CCK 8 and so for these antisera results have been expressed relative to standard G17 only.

Table 2 Concentration of immunoreactive components in extracts of the cortex (hog and dog) or whole brain (rat)

Species	n	Concentration of components in brain (pmol g ⁻¹ : CCK 8 equivalent)		
		BP I	BP II	BP III
Hog	5	16.9±3.1	95.0±33.0	11.2±1.1
Dog	3	14.4±3.7	58.1±20.6	18.1±7.5
Rat	5	30.6±6.9	149.0±20.6	27.5±6.2

Radioimmunoassays were performed using antiserum 1296 and results expressed relative to standard CCK 8. Concentrations were estimated by integration of peaks in Sephadex G25 eluates and calculated on the basis of wet weight of tissue from which the extract was prepared.

the components and, by analogy with other CNS peptides (substance P, somatostatin), a possible role as neurotransmitters or releasing factors deserves consideration.

Technical assistance was provided by Mrs Elaine Clark, Miss Carol Higgins and G. Laing. Antisera C and 2716 were gifts from Drs S. Bloom and J. Rehfeld, respectively. Standard peptides were gifts from Professor R. A. Gregory and Dr H. J. Tracy (G34 and G17), Professor G. W. Kenner (C-terminal octapeptide, hexapeptide and tetrapeptides of G17), Dr V. Mutt (20% porcine CCK), Squibb Institute of Medical Research (CCK 8), and Farmitalia Ltd (caerulein). This work was supported by a grant from the MRC.

Visual contrast sensitivity of a 6-month-old infant measured by the evoked potential

THE visual contrast sensitivity of the human infant has previously been measured using behavioural methods, in which psychophysical thresholds have been inferred from visual preferences¹. In this paper we report a preliminary investigation of contrast sensitivity, as measured by the amplitude of the evoked cortical response, in a 6-month-old infant. These results are compared with behavioural measurements on the same infant, and with adult data obtained psychophysically and from evoked cortical responses.

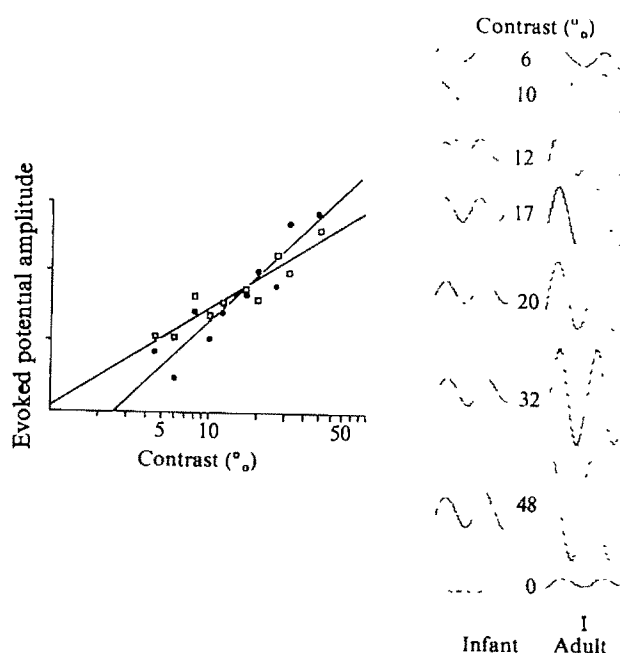

Campbell and Maffei² measured the visual evoked cortical response to a phase reversing sinusoidal grating and found that a linear relationship existed between the logarithm of contrast and the amplitude of the evoked potential. By extrapolating a regression line through such a plot to zero voltage, the psychophysical threshold could be predicted³. This relationship found in adult evoked potential measurements has been used in the present study to indicate thresholds for contrast in a situation where direct psycho-

physical methods are not possible, that is, in human infants.

The stimuli were vertical gratings of sinusoidal luminance profile, whose phase was reversed at 10 Hz. They were generated on an oscilloscope screen by established methods^{4,5}, with a mean luminance of 300 cd m⁻², and subtending an angle of 20° at 57 cm. To ensure that evoked potentials for different contrast levels were comparable in spite of possible artefactual changes over time, the various contrasts for a given spatial frequency were presented repeatedly in short blocks randomly interleaved within a particular run, which lasted about 10 min. Each block lasted 5.1 s. Control blocks, in which the contrast was set to zero, were included in each run. The infant was held sitting 57 cm from the display screen (110 cm for runs with spatial frequency higher than 5 cycles per degree). Between the infant and the display there was a 70% reflecting mirror arranged to superimpose the image of an active face on the stimuli, which served to maintain the infant's attention.

Evoked potentials were recorded from both the infant and the adult by means of 2-mm Beckmann electrodes. One electrode was placed 1 cm above theinion and the other 3 cm temporally: the signals from these were differentially amplified 100,000 times, with an earth electrode placed behind the ear. The amplified signal was filtered (by a Kemo VBF/3/J filter) with a passband of ±2 Hz centred on the second harmonic of the frequency of phase alternation (20 Hz). The filtered signal was fed into an analog input channel of a PDP-11/10 computer which maintained separate averages of the signal for each contrast level used, and also controlled the stimulus contrast and phase alternation. These averages were of a 100-ms sweep and therefore contained two cycles of the second harmonic signal. The first 100 ms of each 5.1-s block were not included in the average, to avoid the effect of initial transients due to the contrast change. The averaging could be interrupted when the infant was not attending to the screen.

Fig. 1 Right, averaged evoked potentials (500 sweeps) for a series of contrast levels, from the infant and adult subjects. Spatial frequency: 0.3 cycles per degree. The bottom traces were obtained with no grating present. Scale: 200 × 10⁻⁹ V per sweep (adult), 50 × 10⁻⁹ V per sweep (infant). Left, plot of amplitude of these potentials against contrast (logarithmic scale). ●, Adult data; □, infant data. Regression lines are shown for each subject. The amplitudes have normalised for this plot.

Fig. 2 *a*, Comparison of the contrast sensitivity functions for the adult (Δ) and infant (\bullet), as derived from the amplitude of the evoked potential. The curves are fitted by eye. Each point is an average of several runs. *b*, Comparison of the psychophysical contrast sensitivity for the adult (Δ) and the behaviourally determined contrast sensitivity function for the infant (\circ). The curves from Fig. 2 *a* are repeated in this figure to aid comparison between psychophysical and evoked potential measures.

In general 500 sweeps were averaged at a given contrast, although for some low contrasts extra blocks were included in the program to obtain a signal of sufficient amplitude. The averaged signals, which because of the narrow pass-band were approximately sinusoidal, were displayed, plotted on an X-Y plotter, and the peak-to-trough amplitude was put out by the computer. Signals have only been included in the results if their peak-to-trough amplitude was at least 20% higher than that measured in the average for the zero contrast control blocks.

The subjects were tested for responses to spatial frequencies ranging from 0.1 to 15 cycles per degree, and contrasts ranging from 4% to 50%, for each frequency. Psychophysical thresholds for the adult were measured with the same apparatus, using a yes-no forced choice method with a double random staircase procedure under the computer's control. The trials near to threshold were interleaved with high contrast displays in a similar sequence to that used for the evoked potential measurements and the screen was viewed through the 70% mirror. Behavioural data on the infant were gathered using the method of fixation preference assessed by two-alternative forced choice by a 'blind' observer*. Stimuli were presented on two oscilloscopes at a distance of 40 cm from the infant, subtending 15° each and separated by 9°. One screen displayed a horizontal test grating and the other a blank field matched in mean luminance. The behavioural threshold was defined as the contrast level at which the observer could make 70% correct judgements of the side to which the stimulus was presented. This was obtained by a modified staircase procedure.

Refraction of the infant subject showed that he was about 1 D hypermetropic with 0.75 D of astigmatism in each eye. He should therefore have had no difficulty accommodating to the stimulus distance. The adult subject was emmetropic.

Figure 1 shows a series of averaged signals for a single spatial frequency (0.3 cycles per degree) and increasing contrast for both the infant and adult subjects. The peak-to-trough amplitudes of the signals of each series were plotted against log contrast and the linear regression line extrapolated to give the contrast for zero amplitude. These extrapolated contrasts are plotted in Fig. 2 *a* as a function

of spatial frequency, for both the infant and the adult subjects. Curves have been fitted to these by eye. Plotted in Fig. 2 *b* are the psychophysically or behaviourally obtained contrast sensitivities for each subject, with the curves of the evoked potential results from Fig. 2 *a*.

For the adult, the extrapolated evoked potential "threshold" estimates lie close to, but in most cases slightly below, the psychophysical thresholds. This is compatible with previous findings^{2,3}. The behavioural measure on the infant gives a lower limit on the estimate of sensitivity. This in fact coincided rather closely with that derived from the evoked potential measurements (Fig. 2 *b*).

In the case of the low spatial-frequency stimuli, it is not possible to determine from our data whether the evoked potentials are generated by the spatial pattern, or by a frequency-doubled response to flicker⁷. When modulation is both spatial and temporal, however, psychophysical thresholds can also be distinguished by the detection of either pattern or flicker^{8,9}. The uncertainty about the origin of the evoked potential does not therefore exclude a comparison with the behavioural data, but it does indicate a need for caution in extending the results to different temporal conditions, such as a static pattern.

The use of evoked potentials allows us to compare the same measure of sensitivity, employed on both infant and adult. Figure 2 *a* shows that for low spatial frequencies the contrast sensitivity derived in this way is very similar for both subjects. At spatial frequencies of 2 cycles per degree and above, however, the adult is shown to be markedly more sensitive. In making these comparisons, it should be borne in mind that the infant and adult visual systems may show differences in temporal as well as spatial response.

We therefore conclude: (1) that the neural mechanisms determining contrast sensitivity at low to medium spatial frequencies have matured by 6 months of age to close to the adult level (this is consistent with the finding¹⁰⁻¹² that the optimum check size for checkerboard-evoked potentials is similar in the 6-month-old and the adult). However, the neural mechanisms determining high spatial-frequency sensitivity are not fully mature at this age. (2) Measurements of contrast sensitivity by means of the visual evoked potential are possible in infants and give data consistent with behavioural methods. It may prove a valuable clinical tool for the early diagnosis of visual problems.

We thank the MRC for support, Dr P. Lennie for the use of his computer program, Professor H. B. Barlow for the use of the computer, and Mr D. Thomas for the refractive examination. We are grateful to Hugo Braddick for being such a patient subject.

The 'cerebellum' and the control of eye movements in cephalopods

THE cybernetic principles involved in the control of locomotion in vertebrates include feed-forward and feedback between the optic and vestibular systems, through a series of control centres, including the cerebellum. Cephalopod molluscs also show swift and well controlled locomotion and have eyes and static organs, but there is little detailed evidence as to how the information from these controls movement. The basal lobes of the supraoesophageal part of the brain are known to be higher motor centres, but this is, at best, a vague term. The new studies of these lobes and of the statocyst by my colleagues and I that are reported here show more clearly the part they play in the control of behaviour. Their organisation proves to be basically similar to that of the comparable systems of vertebrates.

To the many parallels between the organisation of cephalopods and vertebrates described by Packard¹ we can therefore now add that the control of movement of the eyes and body involves a system similar to the cerebellum. The resemblances and the differences between the two systems may help towards understanding of the principles of movement control. In both there is a direct feed-forward from angular acceleration receptors to the oculomotor centre and a visual feedback system involving numerous fine parallel fibres (Fig. 1). From the verte-

Fig. 1 *a*, Diagram of the oculomotor control system in the squid arranged to show its correspondence to that of a mammal. *b*, The oculomotor control system in a mammal (copied, with permission, from Ito²). brate vestibular organs, the pathway is through the vestibular nucleus²; in cephalopods fibres from the statocyst itself end in the oculomotor centre in the lateral pedal lobe (Fig. 2). It is these fibres that must be acting in the fast phase of nystagmus in *Sepia*³. In both groups the vestibular information reaches the eye muscles also through a second route in which it is combined with visual information. In vertebrates this route is through the flocculus of the cerebellum, whose Purkinje axons have been shown to exert an inhibitory influence on the neurones of the vestibular nucleus in rabbits⁴. In cephalopods the corresponding pathway is from the statocyst to each member of a set of basal lobes and from there direct to the oculomotor neurones. The visual input to the vertebrate cerebellum comes through the accessory optic tract and the inferior olive and also by mossy fibres by way of another nucleus (Fig. 1)⁵. Stimulation of the optic disk inhibits the vestibular neurones with a delay of 12 ms and of the inferior olive after 3 ms². In cephalopods the visual pathway is again through the basal lobes and there is good evidence of optokinetic nystagmus^{3,6,7}. Electrical stimulation of the basal lobes produces movements of the eyes, as well as of the head, arms and fins⁸.

Both vertebrates and cephalopods thus use a direct feed-forward control from the statocyst and a feedback from the eyes through cerebellar-type systems. The experiments of Messenger and Collewijn show clearly that the two influences together are necessary for steady visual control. They constitute a classical set of evidence for the effectiveness of such a double system.

The functional parallels between vertebrates and cephalopods make it especially interesting that the cephalopod basal lobes resemble the cerebellum in structure. There has been evidence for some time that the parallel fibres in the peduncle lobe, situated on the optic tract of cephalopods (shown in Fig. 3) resemble the granule cells of the cerebellum⁹⁻¹¹. It has now become clear that this lobe is part of a much more extensive system including the basal lobes of the brain, serving to regulate movement of the eyes and of the whole animal. The arrangement is similar in octopuses and squids but the plan has become much clearer by a recent study of squids, where some of the fibres are larger¹².

The system consists of four lobes on each side of the animal, each with a different orientation (Figs 2 and 4). The outstanding feature of each lobe is a set of parallel fibres. The region known as the anterior basal lobe contains two of these sets of

Fig. 3 Parallel fibres of the peduncle lobe of the squid (*Loligo*). Drawing from a Golgi preparation¹⁰. The optic lobe lies to the right and fibres are shown running to it. The large cell carries an output fibre with axon proceeding to the oculomotor or other motor centre. The input fibres from the optic lobe and statocyst are not shown.

fibres lying in the transverse plane. One set, the posterior anterior basal, runs transversely. The other, the anterior anterior basal, runs across the midline and then down vertically at the sides. A third set is in the median basal lobe, which although it is a more complicated region has similar parallel fibres running transversely, approximately in the horizontal plane. The fourth set of parallel fibres is in the peduncle lobe, running dorsoventrally in the sagittal plane in squids but antero-posteriorly in octopods. The four lobes together thus make a sort of 'cerebellum' with motor control functions.

These lobes all receive fibres from the optic lobes and from the statocysts (Fig. 2). They send fibres to the motor centres for the movements of the eyes and body, and others back to the optic lobes. They thus have essentially the same functional relations as the cerebellum, lying between vestibular and optic centres and serving for integrated visuostatic control of movement. It is therefore very striking to find that there are also similarities of internal organisation¹¹. The inputs of each lobe of the system in cephalopods may be listed thus. (1) Dorsal optic fibres apparently preserving the somatotopic plan of the optic lobe; it is suggested these may serve for tracking. (2) A ventral optic input of a few very large fibres from a region at the base of the optic lobe, perhaps involved with initiating attack. (3) Fibres from the statocyst. (4) Fibres from the giant cell lobe, perhaps related to escape movements. (5) Numerous fibres from the corresponding opposite lobe. (6) Numerous fibres from each of the other basal lobes.

The output is not quite the same for all the lobes but each sends to the following destinations. (1) To the oculomotor centre controlling the four eye-muscle nerves. (2) To the regions con-

Fig. 4 Horizontal section of the supraoesophageal lobes of a small *Loligo*. Cajal stain, showing the positions of the four basal lobes on each side.

trolling the funnel and fins (for steering). (4) To the giant cells that initiate the jet. (5) A reverse projection to the optic lobe, allowing for 'efference copy' ('corollary discharge')¹³⁻¹⁵.

The details of the organisation within the peduncle lobes are beginning to be known^{9,10,16}. Some of the parallel fibres are the T-shaped processes of small "granule" cells and may run for the width of the lobe (1-2 mm) (Figs 5 and 6). They are about

Fig. 5 Golgi stained preparation of peduncle lobes of the small squid *Alloteuthis*, showing the fine parallel fibres and others crossing them.

Fig. 6 Golgi preparation of *Alloteuthis*. Retouched photograph showing especially the collateral dendrites of the fibres that cross the parallel-fibre bundles.

0.3 μm in diameter and carry a series of collaterals, some making synapse with other parallel fibres. The afferents from the optic lobes branch among the bundles. Other cells have fibres that turn down across the parallel fibres to the basal region, from which the output fibres of the lobe arise (Fig. 6). These may thus serve to receive signals from the parallel fibres and pass them to the output cells, but the details of the connectivity are not yet clear. The parallel fibres in the anterior basal lobes are so similar to those in the peduncle lobes in transmission electron micrographs that it is difficult to distinguish between them¹⁶. All the sets of parallel fibres have a characteristic fluorescence, possibly due to 5-hydroxytryptamine, which is not found elsewhere in the brain¹⁷.

Evidence from electrical stimulation and surgical removal confirms that these lobes are concerned with the control of movement of the eyes and body^{9,18,19}. After unilateral lesions in the anterior basal lobe, persistent circling with the lesioned side at the centre has been seen in *Sepia*¹⁸ and *Octopus* (personal observations). After the bilateral removal of the peduncle lobes in *Octopus* there are various motor defects and movements are jerky and less precise^{9,19}.

The pattern of control of movement of the eyes and of the whole animal thus shows remarkable similarities between cephalopods and vertebrates, in spite of the fact that the gross anatomical entities are totally different. The need to monitor the animal's own movements is presumably met by the signals from the cristae of the statocyst, which run in distinct planes, providing information about angular accelerations^{20,21}. The presence of the extensive reverse pathways from the centres in the basal lobes to the optic lobes meets the need to compare performance with internally generated goal specifications. It has been common since the work of von Holst to regard this as a (relatively simple) process of subtraction. As pointed out by MacKay¹⁵, however, the process may be much more complex than this and it is interesting that the information is sent to the optic lobes, which probably act as what he would call a sensory evaluator.

The presence of systems of parallel fibres is especially intriguing and it is tempting to relate it to the hypothesis of Braitenberg²² that such systems provide for the timing of ballistically controlled movements, which are of course a marked feature of cephalopod behaviour. Whatever may be

their function the fine parallel fibres seem to be an essential feature of such systems.

I thank the Wellcome Trust for assistance with this work, Miss P. R. Stephens for technical assistance, and Drs M. Nixon and J. B. Messenger for help in the preparation of this article. I also thank the Directors and Staff of the Marine Biological Laboratory at Plymouth, and the Zoological Station at Naples.

Effect of riboflavin on red-cell metabolism of vitamin B₆

THE red cell is an active site for the conversion of pyridoxine to physiological forms of vitamin B₆. Pyridoxine phosphate is first formed by a kinase and then converted to pyridoxal phosphate by an oxidase, followed by dephosphorylation to pyridoxal, the form which is released into plasma¹. In a large proportion of the patients with homozygous or heterozygous β -thalassaemia whom we have studied, there was a much reduced *in vitro* rate of red-cell conversion of pyridoxine, a familial characteristic inherited separately from thalassaemia, and also found in some haematologically normal subjects^{2–4}. This rate of conversion, whether reduced or normal, is increased by incubation of blood with riboflavin¹, possibly through synthesis in the red cell of flavin mononucleotide (FMN) from riboflavin⁵, which then stimulates the pyridoxine phosphate oxidase⁶, a flavoprotein⁷. In order to study the *in vivo* effect on red-cell metabolism of B₆, riboflavin was administered to one of the haematologically normal subjects with a greatly reduced red-cell conversion rate of pyridoxine. The rate increased to normal within 3 weeks. Here we report the details of this study.

The *in vitro* red-cell conversion of pyridoxine was studied by incubating 500 ng pyridoxine (as pyridoxine-HCl; Sigma) per ml of blood at 37 °C for periods up to 2 h as described previously¹. The *L. casei* microbiological assay was used to measure pyridoxal and pyridoxal phosphate^{1,8}. Pyridoxal phosphate cannot be measured as such, for the *L. casei* measures only pyridoxal directly. Therefore, blood was first acid-hydrolysed in order to free pyridoxal phosphate from protein and to convert it to pyridoxal. The sum of pyridoxal phosphate plus pyridoxal was therefore measured in a hydrolysate and represents the total conversion to active forms. This was expressed as a percentage of the added pyridoxine.

The subject studied was a healthy woman aged 65 yr with a haemoglobin concentration of 1.4 g dl^{-1} and with no evidence of thalassaemia. Her red-cell conversion rate was the slowest of five "slow converters" found among the control subjects. On two occasions with an interval of a year the amount converted was 1.9% and 2.3% per g $\text{Hb} \times 10^{-2}$ at 1 h which was similar to the lowest values found associated with thalassaemia^{3,4}. Her son and daughter had values intermediate between those of their mother and their father whose conversion of pyridoxine was normal. In *in vitro* studies riboflavin or FMN was incubated with blood of the subject and her son, and both compounds significantly stimulated the conversion of pyridoxine.

The *in vitro* red-cell conversion of pyridoxine in the subject was measured immediately before she started a course of riboflavin (Fig. 1). She took 10-mg tablets twice a day for 8 weeks. The conversion of pyridoxine to active forms was measured 1, 3 and 8 weeks after starting this treatment. She then stopped taking riboflavin and the conversion was measured at intervals over 17 weeks. The amount of pyridoxine converted to active B_6 forms after incubation for periods up to 2 h is compared for eight of 14 tests done during the 25 weeks (Fig. 1), and these are compared with the mean amount converted in 60 control subjects.

After one week on riboflavin the rate of conversion of pyridoxine had markedly increased. The amount converted by 1 h increased from 33 to 53% and after 3 weeks had increased further to 87%, which was equivalent to 6.2% per g $\text{Hb} \times 10^{-2}$ and was well within the normal range (5.0 to 8.6 mean 6.6% per g $\text{Hb} \times 10^{-2}$). After 8 weeks on riboflavin the conversion of pyridoxine in this subject was above the mean found in control subjects. After stopping riboflavin, the rate decreased considerably within the first 3 weeks, and continued to decrease steadily. Only by the seventeenth week, however, had the amount of pyridoxine converted at 1 h (2.3% per g $\text{Hb} \times 10^{-2}$) dropped as low as before treatment. It is interesting that the duration of her increased conversion rate corresponds approximately to the normal lifespan of red cells.

The fact that riboflavin administration resulted in a marked increase in the red-cell conversion rate of pyridoxine in this subject strongly suggests that pyridoxine phosphate oxidase is the defective enzyme. A similar though probably more rapid pattern of activation of another red-cell flavin enzyme, glutathione reductase, has been shown after ribo-

flavin administration either when the enzyme activity was originally normal or was reduced⁹. But the prosthetic group for glutathione reductase is flavin adenine dinucleotide (FAD) whereas for pyridoxine phosphate oxidase (an enzyme equally effective in the oxidation of pyridoxamine phosphate¹⁰) it was found to be FMN¹¹. The prompt response of both these enzymes to riboflavin administration is presumably explained by the fact that mature red cells take up riboflavin and synthesise the riboflavin nucleotides, FAD and FMN⁵.

The significance of the ability of the red cells to convert pyridoxine to physiological forms of vitamin B_6 is not yet understood. The considerable uptake of pyridoxine by red cells, far in advance of the rate of conversion^{1,4} suggests that a significant proportion of ingested pyridoxine is metabolised by the red cell (6% of a 40-mg oral dose as in the red cells at 20 min as well as another 3% which has passed into the plasma most probably after conversion in red cells). Vitamin B_6 is known to take part in the transport of amino acids in and out of cells^{12,13} and the red cell plays an important role in the transport of amino acids¹⁴. It is therefore possible that the conversion of pyridoxine (and pyridoxamine¹) in the red cell could be linked to amino acid transport as has been discussed at length in another paper⁴.

In vitro studies in control subjects with normal conversion rates and in patients with thalassaemia with reduced rates demonstrated an increase in the red-cell conversion rate of pyridoxine after incubation of blood with riboflavin or FMN. Detailed *in vivo* studies with riboflavin are not yet completed in these subjects, but we have shown that in β -thalassaemia the rate increases to normal in both heterozygotes and homozygotes after oral administration of riboflavin, as in the subject reported here. In a previous study we found that the red-cell conversion rate of pyridoxine was usually normal in mild homozygous β -thalassaemia (thalassaemia intermedia) but apparently was reduced in the majority of patients with transfusion-dependent β -thalassaemia¹. It is conceivable that the correction of this defect by administration of riboflavin may have some beneficial effect.

This work was supported by grants to Professor D. L. Mollin from the Wellcome Trust. We thank Professor D. L. Mollin and Dr J. A. Child for their interest and advice, and Dr P. J. N. Cox for permission to study his patients.

Polymerisation of membrane tubulin

AMPLE evidence now exists that, in addition to soluble, cytoplasmic tubulin, many tissues contain variable proportions of particulate tubulin as judged from colchicine-binding studies¹⁻⁶. This colchicine-binding activity is not contamination from cytoplasmic microtubules, and is associated with a fraction enriched in plasma membrane markers⁶. The activity exhibits the ligand-binding properties of purified tubulin and reacts with antibodies against soluble brain tubulin. Finally, when the binding activity is solubilised from membranes it exhibits normal binding behaviour toward antimicrotubule agents, normal thermal lability, and normal interaction with antibody⁶. What was not clear was whether this tubulin could participate in polymerisation reactions to form microtubules. We report here that solubilised, labelled tubulin copolymerises with cytoplasmic tubulin through repeated cycles of polymerisation and depolymerisation.

Male guinea pigs of strain 13-N (250–300 g) were injected intraperitoneally with 5 mCi ³H-leucine (61 Ci mmol⁻¹) and whole brains were collected 60 h and 8 d thereafter for use in experiment 1 and 2, respectively. The brains were homogenised in medium containing 0.25 M sucrose, 1 mM dithiothreitol and 3 mM Tris-HCl buffer, pH 7.4. Membranes were prepared as previously described⁶ with additional washes to remove possible cytoplasmic contaminants. To check for completeness of removal of such contamination ³H-leucine-labelled cytoplasmic brain tubulin was added to unlabelled brain homogenates from which membranes were subsequently prepared. All soluble tubulin was removed after the third wash of the membranes (Table 1). In agreement with our earlier studies⁶, it seems that tubulin found in the membrane fraction is firmly attached and not an artefact of the isolation procedure.

Fig 1. Copolymerisation of solubilised membrane-bound tubulin with cytoplasmic rat brain tubulin. The ³H-labelled guinea pig brain membranes (5.2 mg ml⁻¹), isolated as described in Table 1, were suspended in 0.4% of Nonidet P-40 at 4 °C for 30 min and then centrifuged at 100,000g for 20 min at 4 °C. The supernatant, which contained solubilised membrane-bound tubulin, was mixed with an equal volume of 100,000g supernatant of rat brain homogenate and to the total mix an equal volume of 8 M glycerol in polymerisation buffer was then added. The polymerisation and depolymerisation was carried out according to Shelanski *et al.*⁷ and repeated seven times. After each cycle of polymerisation the pellet, which contained microtubules, was suspended in the minimum amount of polymerisation buffer. An aliquot was counted for radioactivity and protein was determined. Experiments 1 (curve *a*) and 2 (*b*) were carried out with guinea pig brain labelled for 60 h and 8 d, respectively.

Fig. 2 SDS-disc gel electrophoretic analysis of copolymerised membrane bound tubulin with cytoplasmic rat brain tubulin. The sample analysed was from experiment 2, Fig. 1, after seven cycles of polymerisation and depolymerisation. An aliquot of 900 c.p.m. (75 µg) was electrophoresed on 5% acrylamide, 0.2% bisacrylamide and 0.1% SDS gel according to Weber and Osborne⁸ in phosphate buffer (pH 7.1). The samples were run at a current of 4 mA per tube at 23 °C until the tracking dye reached the end of the gel. The gels were stained with 0.02% Coomassie brilliant blue in 50% methanol and 9% acetic acid and destained in 5% methanol and 7.5% acetic acid. *a*, The gel was scanned at 520 nm on a Gilford spectrophotometer with a linear transport attachment; the ordinate is linear in absorbance. *b*, The gel was sliced into 1-mm disks, digested in 0.2 ml of 30% hydrogen peroxide at 37 °C for 48 h, and then counted in Aquasol.

Solubilisation of membrane tubulin using Nonidet P-40 was carried out as previously described⁶, and the soluble radioactivity was mixed with unlabelled supernatant (100,000g for 1 h) and purified through up to seven cycles of polymerisation⁷. Constant specific activity was obtained after the third cycle of polymerisation (Fig. 1). Such repolymerisation to constant specific activity is operationally equivalent to classical recrystallisation to constant specific activity and suggests strongly that the radioactivity of the membranes is either tubulin, or tau or other microtubule-associated protein.

That the radioactivity is, in fact, tubulin was verified in

Table 1 Distribution of added ³H-tubulin in different washings of crude membranes

Tissue treatment	³ H (c.p.m.)
Homogenate	12,080
Soluble supernatant	10,200
1st wash	1,100
2nd wash	200
3rd wash	25
4th wash	<5
5th wash	not detectable
6th wash	not detectable

³H-Tubulin, 12,000 c.p.m., was added to rat brain and homogenised in 3 vol membrane buffer (containing 0.25 M sucrose, 1 mM dithiothreitol, and 3 mM Tris-HCl buffer, pH 7.4). The homogenate was diluted with the same buffer to make it 10% with respect to tissue weight, centrifuged for 10 min at 700g to remove debris and the resulting supernatant solution was centrifuged at 37,000g for 10 min. The pellet was washed with membrane buffer three times and then again three times with polymerisation buffer (containing 0.1 M 2-(N-morpholine) ethane sulphonic acid (MES) (pH 6.4), 1 mM ethylene glycol bis(β-aminoethylether)-N,N'-tetraacetic acid (EGTA), 1 mM GTP, and 0.5 mM MgCl₂) before solubilisation. During the washing with polymerisation buffer, membranes were sonicated (3 s) each time to ensure complete removal of trapped cytoplasmic tubulin.

experiments where seven-cycle purified microtubules were examined by sodium dodecyl sulphate (SDS)-disc gel electrophoresis⁸. More than 90% of the protein migrated as the 55,000-dalton subunit of tubulin (Fig. 2), and all the radioactivity comigrated in this position. It seems likely, therefore, that the membrane radioactivity polymerised to constant specific activity is tubulin, and that this tubulin is normal with respect to its ability to polymerise to microtubules.

Only a small minority of electron micrographs show microtubules in close contact with plasma membranes⁹⁻¹¹, and in most cases a sizeable gap occurs between the ends of microtubules and the membrane. Similarly, freeze-fracture preparations of membranes provide no evidence for microtubules embedded in the membrane. Nevertheless, numerous models have been proposed in which microtubules directly modify membrane behaviour¹²⁻¹⁴. What then is the function of tubulin embedded in the membrane? One possibility is that it acts as a nucleation centre for microtubule polymerisation and that this region of the microtubule does not survive the usual fixation for electron microscopy. Indirect evidence that this may be so has been provided by Becker *et al.*¹⁵ who showed specific, temperature-sensitive, non-radiative energy transfer between fluorescein-labelled membranes and rhodamine-labelled tubulin. Whatever its role, the tubulin bound to membranes seems to be identical to cytoplasmic tubulin in all respects, except that it has greater thermal stability, and must be taken into account in interpreting the effects of antimicrotubule drugs on membrane behaviour.

We thank Dr A. Burkhardt for providing us with the labelled tissue.

Operon controlling motility and chemotaxis in *E. coli*

THERE has been extensive study of the genetic basis for flagellar formation^{1,2}, motility³ and chemotaxis^{4,5} in *Escherichia coli*. But in order to understand the specific mechanisms involved in these processes it is necessary to identify the gene products. We recently showed how *E. coli*- λ hybrids could be used to identify flagella-related proteins⁶ and we have subsequently isolated two phages that carry the genes directly involved in flagellar functions. One phage (Fig. 1a, λ fla2) carries *flaI*⁷ which regulates the synthesis of flagellar proteins and *mot*,

which is necessary for flagellar rotation. λ fla2 also seems to carry part of the *cheA* gene⁸, which is concerned with regulating flagellar rotation in response to chemotactic signals. It is thought to carry only part of the *cheA* gene because the phage does not show genetic complementation when it is introduced into *cheA* mutant strains. It does, however, produce wild-type recombinants with one *cheA* mutant (e14t1) but not with another (e14q1) (Fig. 1b). Furthermore, the hybrid- λ phage that carries the adjacent segment of DNA (Fig. 1a, λ fla3) also does not show complementation when it is introduced into *cheA* mutant strains. It gives wild-type recombinants with the *cheA* mutant e14q1 but not with the strain that carries the allele e14t1 (Fig. 1b). On the basis of these observations we concluded that the endonuclease (*EcoRI*) which was used to generate the DNA fragments that were cloned cleaved the *cheA* gene, and that λ fla2 carries the promoter proximal part of the gene⁸ while λ fla3 carries the distal part of the gene (Fig. 1a).

Two polypeptides FP39 (flagellar protein, molecular weight 39,000) and FP31 were synthesised after infection of ultraviolet-irradiated cells with λ fla2 and its derivatives. FP31 was identified as a product of the *mot* gene but no assignment could be made for FP39. Two possibilities were considered⁹: (1) that it was a polypeptide fragment representing the promoter proximal part of the *cheA* gene or (2) that it was the product of a second *mot* cistron which mapped between *mot* and *cheA*. To distinguish between these possibilities, a new phage was constructed that restored the continuity of the *cheA* gene. The first hypothesis predicts that the polypeptides coded for by this phage will include a new larger polypeptide replacing FP39. The second hypothesis predicts that FP39 will remain and that an additional polypeptide corresponding to the integral *cheA* gene will appear.

The steps involved in the construction of the new phage are summarised in Fig. 1a. λ fla18 was derived from λ fla2 and λ fla18 Δ 2 carried a deletion which removed the *flaI* gene and part of the *hag* gene as well as one *EcoRI* site⁸. The *mot* gene and part of the *cheA* gene (Fig. 1b) remained fused to the right arm of lambda. λ fla42 was derived from λ fla3, a deletion removed the *flaG* and *flaH* activities. λ fla42 Δ 13 carried a further deletion which removed the *cheB* gene activity as well as an *EcoRI* site leaving the other part of the *cheA* gene fused to the left arm of lambda. *EcoRI* endonuclease digestion and subsequent ligation was used to construct a new phage (λ fla52) composed of the left arm of λ fla42 Δ 13 and the right arm of λ fla18 Δ 2. The new phage carried *mot* and could form recombinants and showed complementation with *CheA*⁻ strains (Fig. 1b). Even in liquid culture *CheA*⁻ strains that showed the characteristic smooth swimming phenotype regained the ability to 'tumble' within 25 min after infection by λ fla52. Thus we conclude that λ fla52 carries the gene that can restore functional *cheA* activity.

Figure 2 shows the flagellar proteins that are synthesised after infection with hybrid λ phages. λ fla42 specifies the synthesis of the *cheB* gene products (including FP38 and FP8), the *hag* gene product, the triplet protein(s) (FP62) and a low molecular weight polypeptide (FP12). The *cheB* gene products, the "triplet" protein(s) and the low molecular weight polypeptide will be discussed in detail elsewhere. For our present purposes the "triplet" bands serve as a convenient outside marker on the left-hand part of λ fla52. Infection with λ fla42 Δ 13 results in the "triplet" and flagellin bands while λ fla18 Δ 2 gives rise to FP31 and FP39 as well as a new band FP43, which is associated with the deletion that removes flagellin activity and serves as a convenient marker for the right arm of lambda. λ fla52 specifies the synthesis of three new bands that are flagellar specific and could not have been predicted from the properties of the parent phages. The bands will be referred to as FP76, FP66 and FP12.

The restoration of the continuity of *cheA* resulted in the appearance of new polypeptides but did not affect FP39. This suggests that FP39 is not a product of the *cheA* gene but rather results from another gene between *cheA* and *mot*. Armstrong and Adler³ showed that strains carrying *mot* mutants fell into

Fig. 1 a. Construction of λ-hybrid phage carrying intact Mocha operon. The top line shows a portion of the *E. coli* genetic map. Arrows below the line indicate the position of *EcoRI* endonuclease sites. The construction of λfla3, λfla2, λfla18, λfla1Δ4 as well as the methods for genetic characterisation and endonuclease mapping have been described^{6,8}. λfla42 was made from λfla3Δ1 (a deletion of λfla3 which removed *flaG* and *flaH*) and λfla1Δ4. Deletions were selected by the method of Parkinson and Huskey¹². The heavy line indicates the presence of the appropriate gene, detected by complementation or recombination. CheA(t1) and cheA(q1) refer to the ability to form recombinants with strains carrying these alleles. The light areas indicate specific deletions. λfla52 was constructed by mixing *EcoRI* endonuclease-treated DNA from λfla42Δ13 and λfla18Δ2 followed by annealing and ligation. After transfection 400 plaques were picked and tested. They had the genetic properties of all four possible combinations, λfla42Δ13, λfla18Δ2, λfla1Δ4 and λfla52. Three plaques with identical properties were isolated: λfla52, λfla55 and λfla57. **b.** Genetic characterisation of λfla52 and its parent phages. The phages were streaked across tester strains⁸ carrying a *mot* mutation (MS5020, a λ lysogen of² MS797). A *cheA* mutation (MS5034, a λ lysogen of e14t1) and another *cheA* mutation (MS5033 a λ lysogen of e14q1) (both obtained from J. S. Parkinson). Recombination is recognised by the formation of swarms (diffuse spreading and concentric circles); complementation is scored by the dense short trails close to the region of infection. For example, the infection of MS5020 by λfla18Δ2 shows both recombination and complementation, MS5034 shows only recombination and MS5033 shows neither.

two groups, *motA* and *motB*. They could not, however, exclude the interpretation that these represented intracistronic complementation within a single *mot* gene. In *Salmonella*⁹ there are apparently two cistrons, *motA* and *motB*. We tested a large number of deletions of the phage for complementation and recombination with strains carrying *motA*, *motB* and *cheA* mutations. Figure 3 shows that the deletions of λfla52 could

distinguish clearly between *motA* and *motB* mutations. Furthermore, with the exception of λfla52Δ7 (which probably represents a deletion within the *motA* structural gene) deletions into *motA* (λfla55Δ1) resulted in loss of expression of *motB* and *cheA* function, although deletions into *cheA* or *motB* had no effect on *motA*. This kind of polarity can best be interpreted in terms of an operon in which the order of transcription is

Fig. 2 Electrophoresis of proteins synthesised in ultraviolet-irradiated cells infected with hybrid λ. Conditions of infection, labelling electrophoresis and autoradiography have all been described^{6,13}. The letters on the left of the figure refer to the bands on the gel: a, FP76; b, FP66; c, triplet, FP62; d, flagellin; e, FP39; f, FP38; g, FP31; h, FP12. Infection of strain 159 with λfla52 results in the expression of proteins coded for by λ as well as those specified by λfla52. Strain 6103 carries the *flaI* mutation and is also a lysogen. The *flaI* mutation specifically represses the synthesis of flagellar gene products and the resident λ represses λ-specific gene products¹³.

motA, *motB* and *cheA*⁸. We refer to this grouping as the Mocha operon. The "triplet" product is not included in the Mocha operon.

Further evidence for an operon-like unit comes from observations on the effects of the deleted phages on the behaviour of *mu*-induced *mot* mutants. When the *mu* genome is inserted in the *motA* gene it eliminates both motility and chemotaxis (J. S. Parkinson, personal communication). When λ *fla52Δ1* (*MotA*⁺ *MotB*⁺ and *CheA*⁺) infected the *mu mot* mutants it restored both motility and chemotactic behaviour (tumbles) in less than 30 min. λ *fla57Δ5* (*motA*⁺, *motB*⁺) restored motility but the cells showed the smooth swimming phenotype characteristic of *CheA*⁻ mutant strains. Neither λ *fla52Δ7* nor λ *fla52Δ11* restored motility, thus both the *motA* and *motB* products are necessary for motility.

The polypeptides that are determined by the deleted phages are shown in Fig. 3. Band FP31 corresponds to *motA*, FP39 corresponds to *motB* and FP76, FP66 and FP12 all correspond to *cheA*. The three *cheA* polypeptides could result from processing of a single polypeptide or alternatively there may be three contiguous genes that code for these polypeptides. In order to distinguish between these possibilities heteroduplexes between λ *fla52Δ7* DNA and λ *fla52Δ1* DNA were formed. λ *fla52Δ1* deletes the triplet band which should map on the left side of the *cheA* gene and should be contiguous with the longer left arm of lambda. In λ *fla52Δ7* only the *motA* activity is deleted, which suggests a small deletion on the right side of the

Fig. 3 Correlation between genetic properties and specific protein synthesis. The table on the top summarises the results of complementation and recombination tests: +, complementation and recombination; R, recombination alone; —, neither. The strains MS5037 (a λ lysogen of strain 448 *motA*), MS5038 (a lysogen of 507 *motB*) and MS5039 (λ lysogen of 483 *motB*) (all obtained from J. Adler) were originally isolated and characterised by Armstrong and Adler³. The acrylamide gel bands are referred to in the same way as in Fig. 2. The intense band above the one labelled *e*, is FP43.

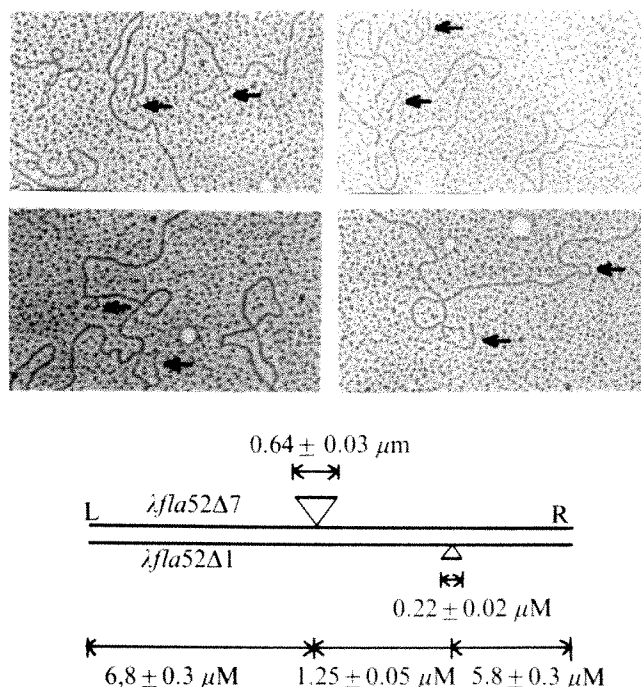

Fig. 4 Heteroduplex maps of λ *fla52Δ7* and λ *fla52Δ1* DNA. Heteroduplex mapping was done according to the procedure of Davis¹⁴: 25 molecules carrying the double loops were photographed in the presence of circular colicin E1 DNA (2.14 μ M). The photographs were traced and the relative contours calculated with a Hewlett-Packard calculator digitiser. The col E1 DNA was used as reference.

motB gene contiguous with the shorter right arm of lambda. The region between these two deletions corresponds to the *motB* and *cheA* genes. Twenty-five heteroduplex molecules with double loops were measured; the results are shown in Fig. 4. The distance between the deletion loops corresponds to 8.5% of lambda, or to 3.7 kb pairs, or to 1,230 amino acids. If all of the DNA is transcribed and translated into protein, this must account for both the *motB* and *cheA* polypeptides. Thus the *cheA* gene product could not have more than 835 amino acids. This is slightly more than half the number of amino acids required to make up three polypeptides with apparent molecular weights of 76,000, 66,000 and 12,000.

We conclude that the *cheA* gene is part of a cotranscribed unit, Mocha. The gene products resulting from this operon include proteins of molecular weight 31,000 and 39,000 that correspond to the *motA* and *motB* cistrons and three polypeptides of molecular weight 76,000, 66,000 and 12,000 that correspond to the *cheA* region of the genome. This region does not have the contiguous coding capacity sufficient to account for unique polypeptides of these sizes. There are various mechanisms that could rationalise this apparent discrepancy, for example, modification or processing of a single precursor polypeptide, or modifications in the transcription or translation processes¹⁰. Analysis of the peptide maps should distinguish between these possibilities.

In any event, if all three polypeptides have a function in chemotaxis, it may help to explain the complexity in the complementation patterns observed with *che* mutants in *E. coli*⁶ and *Salmonella*¹¹.

We thank J. Adler and J. S. Parkinson for strains. The work was supported by a grant from the National Science Foundation.

Ends of bacteriophage Mu DNA

THE temperate bacteriophage Mu does not prefer a specific attachment site on the chromosome of *Escherichia coli* and can apparently engineer the insertion of its DNA irrespective of the host sequences encountered¹. The highly promiscuous, non-homologous integrative recombination between Mu DNA and *E. coli* DNA has prompted a comprehensive analysis of the structure of the Mu genome. The DNA molecules in mature Mu virus particles are linear duplexes of 37-38 kilobases (kb) (ref. 2). When the two Mu DNA strands are separated and reannealed, complete duplexes are not regenerated. Instead, one end is always split into two single-stranded tails, which can be readily seen with an electron microscope^{3,4}. This end of Mu DNA has been identified as the right end or the S end⁵. The single-stranded tails are generally 1.5 kb in length, although occasionally the single strand can be as short as 0.5 kb or as long as 3.0 kb (ref. 6). The non-renaturation of the S end clearly reflects the heterogeneity of the terminal sequences. Studies on the renaturation kinetics of the Mu DNA have implied that *E. coli* sequences at the S end are responsible for the heterogeneity⁷. Allet and Bukhari have proposed that the left end of Mu DNA, the c end, is also not fixed and varies in length by about 100 base pairs⁸. This proposal stemmed from the observation that the DNA fragment cleaved from the c end of Mu by the restriction endonuclease *HindIII* (from *Hemophilus influenzae*) does not give a sharp band on polyacrylamide or Agarose gels after electrophoresis. The heterogeneity of the c end is normally not detectable by electron microscopic techniques.

Bukhari and Taylor have presented evidence showing that the heterogeneity at the S end is a consequence of the headful packaging of Mu DNA from maturation precursors which have *E. coli* DNA covalently linked to the phage DNA⁹. The packaging reaction starts in an oriented manner from the c end and proceeds toward the S end. This inference is supported by partial denaturation mapping studies of Inman *et al.*⁹ They have demonstrated that the S end of Mu is situated at the phage head-tail junction. We report here experiments which demonstrate conclusively that *E. coli* DNA is present at the c end as well as the S end of Mu. We further show that the end sequences represent different parts of the *E. coli* chromosome and that the amount of host sequences at the c end is about tenfold less than those present at the S end.

We hybridised radioactively labelled *E. coli* DNA to the Mu DNA fragments generated by various restriction endonucleases. These experiments were based on the technique

of Southern¹⁰, in which DNA fragments from the Agarose gels are transferred to a nitrocellulose paper and then hybridised with the radioactive RNA or DNA probe. Autoradiography then reveals which, if any, fragments give significant specific hybridisation with the probe. If Mu contains *E. coli* DNA at the ends, only the two terminal fragments would hybridise with the *E. coli* DNA whereas the internal fragments would not.

We cleaved Mu DNA with the restriction endonucleases *HindII* and *HindIII* and *EcoRI* and separated the resulting fragments by electrophoresis in Agarose gels. The sites at which these enzymes cut Mu DNA are shown in Fig. 1 (ref. 8). Both *HindIII* and *EcoRI* are known to cleave Mu DNA at two sites. *HindIII* gives a diffuse fragment of about 1.1 kb from the c end and a fragment of about 7 kb from the S end. *EcoRI* produces a fragment of about 5.1 kb from the c end and of about 10 kb from the S end. *HindII* cleaves Mu DNA at 17 sites, the c end fragment being 4.5 kb in length. No S end fragment could be seen, however, with *HindII*. Presumably *HindII* cuts too close to, and within, the heterogeneous sequences resulting in a whole range of different size fragments.

The hybridisation of ³²P-labelled *E. coli* DNA to Mu DNA fragments generated by *HindII* is shown in Fig. 2. The fragments were first stained with ethidium bromide, photographed under ultraviolet light and then transferred to a nitrocellulose paper for hybridisation. It can be seen in the autoradiograph that only one Mu fragment hybridised with the *E. coli* DNA. We know that this fragment, about 4.5 kb in length, comes from the c end² and as expected is further cleaved by *HindIII*. To show the presence of host sequences at the S end, the fragments generated by *HindIII* and by the combined action of *HindIII* and *EcoRI* were hybridised with ³²P-labelled *E. coli* DNA. As shown in Fig. 3, the fragment representing the S end as well as the fragment representing the c end specifically hybridised with *E. coli* DNA, whereas the other fragments did not.

Because of the heterogeneity of the Mu DNA ends, it is logical to assume that the host sequences do not arise from a specific segment of the host chromosome but that they are derived from all parts of the host genome. To test this assumption, *E. coli* DNA was cut with *EcoRI* or *HindIII* and the fragments were hybridised with ³²P-labelled Mu DNA. Figure 4 shows that whereas calf thymus DNA showed no hybridisation with Mu DNA, all *E. coli* DNA fragments picked up the ³²P label. The general hybridisation could be seen particularly with the larger fragments of *E. coli* DNA in the upper part of the gel. Hybridisation of *EcoRI* fragments of *E. coli* with the purified ³²P-labelled S end and the c end fragments provides results similar to the whole Mu DNA. It can be inferred therefore that all parts of the *E. coli* genome are represented at the ends of Mu DNA. Whether all parts have an equal chance of being present at the end cannot be determined precisely at this time. It can be seen in Fig. 5 that some host fragments stand out more clearly above the general hybridisation background. It is not clear whether these host segments are overrepresented at the ends or whether Mu DNA also has some specific sequences related to sequences in *E. coli*.

The relative amounts of host DNA at the c end and at

Fig. 1 Cleavage map of Mu DNA. Mu DNA is drawn as a solid line calibrated in kilobases. The broken line at the end represents host DNA. The sites at which *HindIII* cleaves Mu DNA are shown by solid circles. The circles above the line indicate *HindII* sites, in the middle of Mu DNA, which have not been ordered with respect to each other. The c end fragment produced by *HindII* is shown as 4.6 kb long segment. Cleavage sites of *HindIII* and *EcoRI* are shown by arrows. A-E, Fragments generated in the presence of both *HindIII* and *EcoRI*.

Fig. 2 Hybridisation with *E. coli* DNA to Mu DNA fragments generated by *Hind*II and *Hind*II + *Hind*III. Bacteriophage Mu particles were purified by caesium chloride density gradient centrifugation; the DNA was extracted with phenol and digested with *Hind*II and *Hind*II + *Hind*III (refs. 6 and 8). The fragments were separated by electrophoresis in 1.4% Agarose slab gels, stained with ethidium bromide and photographed under ultraviolet light, as described by Sharp *et al.*¹¹. To denature the fragments, the gels were soaked in 0.2 M NaOH, 0.6 M NaCl for 40 min and this solution was then replaced by 0.6 M NaCl and 1 M Tris, pH 7.4, for 30 min. After denaturation and neutralisation the fragments were transferred to nitrocellulose paper (Millipore 25 HAWP) as described by Southern¹⁰. The gel strip containing the denatured fragments was placed on a large sheet of Whatman MM paper, wetted with 4×SSC (SSC = 0.15 M NaCl, 0.15 M Na citrate), on a glass plate. A strip of nitrocellulose paper, a strip of Whatman MM paper and some absorbent papers, in that order, were laid on top of the gel strip and the large sheet of Whatman paper was continuously wetted with 4×SSC, with frequent changes of the absorbent papers. The DNA became trapped in the nitrocellulose paper as 4×SSC passed through the gel, drawn by the filter paper¹⁰. After the transfer of the fragments was complete (about 3 h), the nitrocellulose paper was dried, baked in an oven at 65 °C and soaked for a few hours in Denhardt's solution¹² to reduce nonspecific binding of labelled DNA. The hybridisation with denatured ³²P-labelled *E. coli* DNA was then carried out using the standard method of DNA-DNA hybridisation on filters¹². The ³²P-labelled *E. coli* DNA was prepared by growing *E. coli* K12 cells in a low phosphate medium, supplemented with H₃³²PO₄. The hybridisation mixture contained 0.1–0.5 mg ³²P-labelled denatured probe DNA (generally with 2–5 × 10⁵ c.p.m.), 0.5% SDS, in 1× Denhardt's solution and 6×SSC. After hybridisation the nitrocellulose paper was washed extensively in 2×SSC + 0.5% SDS at 60 °C, dried and autoradiographed. For further technical details see ref. 13. The figure shows Mu DNA fragments visualised after ethidium bromide staining (left hand columns) and after hybridisation with ³²P-labelled *E. coli* DNA (right hand columns) Mu *cts62(a)* was grown by induction of strain BU 165 which contains a single copy of Mu *cts62 mom*⁶. Mu *c3(b)* was grown by infection. The position of the *c* end fragment with *Hind*II is indicated by an arrow. This fragment is cut by *Hind*III and thus does not appear in the *Hind*II + *Hind*III digest of Mu *cts62* DNA. The *S* end fragment is too heterogeneous to be seen in these conditions*. Hybridisation with the *c* end fragment is visible in the autoradiograph. Hybridisation with the diffuse *c* end fragment generated by *Hind*III (labelled *Hind*IIIc) is too low to be detected here and is shown in Fig. 4.

the *S* end could be determined by hybridising Mu fragments with varying concentrations of *E. coli* DNA. The *c* end and the *S* end bands were cut out from the nitrocellulose papers after hybridisation and read in a scintillation counter. *E. coli* DNA always hybridised with the *S* end 10–20-fold more than with the *c* end. Since the mean length of the *S* end heterogeneous sequences is about 1.5 kb (see ref. 6), it follows that the *c* end generally has 75–150 base pairs of heterogeneous host sequences.

Fig. 3 Hybridisation with *E. coli* DNA to Mu fragments produced by *Hind*III, *Eco*RI and *Hind*III + *Eco*RI. Mu *c3* DNA fragments visualised after ethidium bromide staining are on the left. Autoradiograph of the same fragments after hybridisation with ³²P-labelled *E. coli* DNA is on the right. The experimental procedure was as in Fig. 2 except that electrophoresis was carried out in 0.9% Agarose gels to resolve large fragments. In each case the most rapidly moving band represents the *c* end and the second band from the top represents the *S* end. In *Eco*RI digest a partial fragment, because of incomplete digestion, can be seen at the top. The marker DNA was a mixture of labelled Mu fragments and an unrelated labelled fragment. The unrelated marker fragment can be seen as a dark band in the autoradiograph. The fragments and their pattern of hybridisation are diagrammatically shown in the insets at the bottom. With *Hind*III and *Eco*RI, the middle fragment of Mu did not show significant hybridisation with *E. coli* DNA, whereas both the *c* end and the *S* end fragments did. With *Hind*III + *Eco*RI digestion, out of 5 fragments (see map in Fig. 2) only B (*S* end) and E (*c* end) hybridised with *E. coli* DNA.

Fig. 4 Hybridisation with Mu DNA to fragments of *E. coli* DNA. Total cellular DNA from KL16, an *E. coli* K12 strain, and from a Mu *cts62* lysogen was extracted three times with phenol and digested with *Hind*III or *Eco*RI. Calf thymus DNA, digested with *Eco*RI, was used as control to check for stringency of hybridisation. Mu DNA was labelled *in vitro* with ^{32}P to high specific activity by the so-called "nick translation technique", as described by Maniatis *et al.*¹⁵. DNase I (1 ng) was added to cause nicks and then the nick translation reaction carried out with DNA polymerase using ^{32}P -labelled nucleotide triphosphates. The DNA bands visualised after ethidium bromide staining are on the left. The brightly stained bands in the calf thymus DNA column are comprised of tandemly-repeated sequences that are represented many times in the DNA complement. No hybridisation of Mu DNA with calf thymus DNA can be seen in the autoradiograph on the right. Hybridisation with *E. coli* DNA can be clearly seen at the top; the intensity of bands in the autoradiograph decreases as fragments become smaller and smaller towards the bottom of the gel. The *Hind*III digest of DNA from a lysogen (BU 1209) shows three prominent bands whereas the *Eco*RI digest of the lysogen DNA shows two very strong bands after hybridisation. These bands, indicated by arrows, represent the prophage Mu DNA. The principle for detecting the integrated Mu genome was as described by Botchan *et al.* for determining the organisation of the simian virus 40 DNA in rat cells transformed by SV40. In the *Eco*RI digest of the lysogen DNA, the top band represents the middle part of the prophage genome and the *S* end junction fragment of prophage and host DNA. The second band represents the *c* end junction fragment. In the *Hind*III digest of the lysogen DNA the top two bands (not completely resolved) represent the middle fragment and the *S* end junction fragment. The third band is the *c* end junction fragment. The size of the end fragments has changed because of fusion with host DNA. The significance of the minor discrete bands in *E. coli* DNA digests, which can be seen after hybridisation with ^{32}P -labelled Mu DNA, remains unclear.

These results provide direct proof that *E. coli* sequences are present at both ends of Mu DNA and that these sequences are picked up from different parts of the chromosome of *E. coli*. The host sequences at the *c* end correspond to 75–150 base pairs. These sequences, as opposed to the *S* end sequences, are generally too short to be seen by electron microscopy of denatured and renatured Mu DNA molecules. It is possible, however, to see them electron microscopically by binding T4 gene 32 protein to the single strands (H. Delius, personal communication).

The host sequences at the *S* end have been postulated to arise by headful packaging of Mu DNA from maturation precursors in which Mu DNA is covalently linked to host DNA. This would mean that the headful packaging of Mu

starts from the *c* end, linked to host DNA, and proceeds toward the *S* end, also linked to host DNA and that the presence of host DNA at the *S* end is a phenomenon of the size of Mu DNA. Experimental evidence has confirmed that insertions in Mu DNA cause a reduction in the length of the *S* end host sequences, as expected from the headful packaging model.

The *X* mutants of Mu, containing an ISI type of insertion of about 800 base pairs¹⁴, show shorter single-stranded tails on denaturation and renaturation⁶. Insertion of a 2.8 kb long translocation element, carrying gene for chloramphenicol resistance, completely eliminates the *E. coli* sequences at the *S* end (Chow and A.I.B., unpublished). Insertions in Mu seems, however, to have no effect on the

Fig. 5 Generation of *E. coli* DNA at the ends of Mu. Two possible models shown are based on the assumption that the maturation precursor contains *E. coli* DNA linked to both ends of Mu DNA. *a*, P recognises a specific site at the *c* end but cuts to the left of the prophage DNA, into the host DNA. The DNA is then folded until a headful is reached at the *S* end. *b*, P recognises a specific site at the *c* end and serves as a nucleation centre for condensing DNA. When a headful is reached, cuts in DNA are made. The cut into *E. coli* DNA near the *c* end is made because the nucleation centre is large, covering a part of the host DNA at the *c* end. The representation is strictly diagrammatical.

size of the host sequences at the *c* end. The *c* end fragment produced by *Hind*III remains diffuse on gels in the case of both small and large insertions in Mu DNA (data not shown). The acquisition of 75–150 host base pairs at the *c* end is apparently a specific event, unrelated to the size of Mu DNA being packaged. Two possible ways in which a small amount of host DNA can be linked to the *c* end of viral DNA are depicted in Fig. 5. It can be postulated that the 'packaging proteins' recognise a specific site, very close to the *c* end of the Mu DNA, cut the DNA to the left of the recognition site and then fold the DNA until a certain size is reached. This would imply an interesting endonucleolytic cut by Mu proteins. Alternatively, the DNA could be condensed by a large packaging complex which covers a part of the host sequences linked to the *c* end such that when the packaged DNA is cleaved from the maturation precursor some host DNA is retained at the end. In any case, cutting into host sequences at the left, and also to the right, of the actual Mu DNA ends ensures that Mu sequences remain intact during the viral life cycle.

Mu is the only viral system known so far in which viral DNA acquires new host sequences during maturation. The normal presence of host DNA at phage ends thus has no precedent. The temperate bacteriophages generally have either cohesive ends or have duplicated end sequences which are used to efficiently convert the linear DNA molecules into circular forms. Bacteriophage Mu falls into a third category. It has heterogeneous sequences at the ends of its DNA and has no obvious means of fusing them to form circular molecules.

Photoformation of polychlorinated biphenyls from chlorinated benzenes

In recent years there has been considerable public concern about polychlorinated biphenyl (PCB) residues in the environment. Many studies have indicated the main causes and the present problems with regard to the contamination by PCBs^{1–6}. Little attention has, however, been given to the possible presence of PCBs in many organic chemicals. We report here the formation of PCBs from some chlorinated benzene compounds by sunlight irradiation, and show that these PCBs have different gas-liquid chromatographic (GLC) profiles from the industrial PCBs.

The following reagent grade chlorobenzenes used as

Table 1 Photoformation of PCBs from chlorinated benzenes*

Chlorinated benzenes	Irradiation (d)				No. of Cl atoms calculated
	0	14	28	56	
MCB	5.5	690	1,060	NA†	1
<i>o</i> -DCB	1.4	940	970	2,270	3
<i>m</i> -DCB	1.1	340	350	520	3
<i>p</i> -DCB	0.7	310	340	1,860	3

1,2,4-TCB	4.0	5,710	8,470	9,770	5
1,3,5-TCB	1.7	56	98	160	5
1,2,3,4-TECB	2.4	680	1,200	4,280	7
1,2,4,5-TECB	4.0	9	26	NA	7
HCB	1.0	36	41	64	5

*p.p.m.

†NA, not analysed.

materials were purchased (Wako Pure Chemical Industries, Ltd, Osaka, Japan); monochlorobenzene (MCB), *o*-, *m*-, *p*-dichlorobenzene (DCB), 1,2,3-, 1,2,4-, and 1,3,5-trichlorobenzene (TCB), 1,2,3,4-, and 1,2,4,5-tetrachlorobenzene (TECB), and hexachlorobenzene (HCB). Twenty grams of each of these were placed in 100-ml Hario brand borosilicate glass-stoppered Erlenmeyer flasks (Shibata Chemical Apparatus Co., Tokyo) which were stoppered and irradiated outdoors in sunlight for 56 summer days in Kochi, Japan.

The separation of PCBs from chlorobenzenes was carried out as follows: 0.1 g of an irradiated chlorobenzene was dissolved in 2 ml hexane, placed on a 20-g, 19-mm interior diameter silica gel column and eluted first with 250 ml hexane which removed MCB, DCBs, TCBs, TECBs and HCB, and then with 300 ml methylene chloride-hexane-acetonitrile (80:19:1) which eluted PCBs. The second fraction was cleaned up with a 10-g Florisil column using 200 ml hexane as eluting solvent. Average recoveries of PCBs in this separation process were 96.9% when the sample has fortified at 100 p.p.m. with KC-500, an industrial PCB.

The quantitation of PCB residues has usually been done by measuring the total peak height of the electron capture GLC response for residue against that of industrial PCB such as KC-500. We did not determine PCBs formed from chlorinated benzenes by the above method because their GLC profiles were not similar to those of industrial PCB. The fraction containing PCBs was perchlorinated using the method described previously^{7,8}. Decachlorobiphenyl formed by perchlorination of a mixture of PCBs was easily detectable as a single peak by electron capture GLC using 1% SE-30 column at 210 °C. The residue values were determined based on the electron-capture response to the decachlorobiphenyl compared with the standard, and then calculated so as to express the amount of PCBs containing an equivalent number of chlorine atoms.

PCBs were determined in all irradiated chlorobenzenes throughout the experimental period. GLCs showing PCB photoformation from a number of chlorinated benzenes are presented in Fig. 1, and the amounts formed are given in Table 1. A single peak due to a substance containing one chlorine atom was found to originate from MCB; PCBs containing three chlorine atoms were photoformed from DCBs; PCBs formed from TCBs almost always contained five chlorine atoms (at least six PCBs were observed in products from 1,2,4-TCB compared with only one PCB formed from 1,2,3-, and 1,3,5-TCB). Several PCBs containing seven chlorine atoms were formed from each of the TECBs; PCBs formed from HCB were found to have four or five chlorine atoms; GLC-MS suggested that the chemical structure was dimethyl chlorobiphenyl but it is unclear where the methyl groups originated: the problem is under investigation.

The reaction mechanism of photoformation of PCBs may

Fig. 1 Electron capture gas-liquid chromatograms of PCBs formed from chlorinated benzenes by sunlight irradiation. The KC series are Kanechlor, industrial PCBs (Kanechlor Chemical Industries Co., Ltd, Osaka). Each peak was determined by GLC-MS and both the GLC peak position and the *m/e* of the molecular ion are shown together with the chlorine content. The chemical structure of substances causing the main peaks of PCBs have been proposed by comparison with GLC reference standard of known chlorinated biphenyls made by Analabs Inc., Connecticut.

involve free radical reactions based on the dehydrochlorination of one molecule from two molecules of the parent chlorobenzene. This is supported by the following: (1) the formation of hydrochloric acid in the reaction mixture; (2) the number of chlorine atoms in PCBs formed by irradiation was one less than those contained in two molecules of the equivalent parent chlorobenzene; (3) PCB formation was remarkably inhibited when the radical scavenger, DPPH(2,2-diphenyl-1-picrylhydrazyl) was added to a chlorobenzene, and the amount of PCB formed decreased to approximately one hundredth in the case of 1,2,4-TCB. Conversely, an increase in photoformation resulted when photosensitizer, benzoyl peroxide, was added, the amount of PCB formed increasing threefold in the case of 1,2,4-TCB; (4) in addition, it is possible to deduce theoretically that 2,5,4'-trichlorobiphenyl is formed from *p*-DCB and 2,4,5,2',5'-pentachlorobiphenyl from 1,2,4-TCB.

Although each chlorinated benzene has strong ultraviolet absorption in the ranges 210–230 nm and 250–300 nm, the borosilicate glass container prevented sunlight at wavelengths less than 300 nm from entering. Therefore, it was impossible to investigate the possible effect of the ultraviolet component of sunlight in these experiments, but PCB formation from chlorinated benzenes under irradiation by ultraviolet light is now being studied.

Previous workers^{9,10} have indicated that some PCBs are products of DDT photolysis. This paper demonstrates that appreciable quantities of PCBs are also formed photo-

chemically from other types of synthetic organochlorine compounds. We suggest that caution should be exercised when manipulating chlorinated benzenes industrially and when handling household insecticides such as *p*-dichlorobenzene.

We thank S. Takahashi (Shimadzu Seisakusho Ltd) for GLC-MS and L. Kovach (JAOAC editorial office) for suggestions in the preparation of this paper.

Colour, song and movement

Peter Conder

BIRDS probably command a greater following at many levels of interest throughout the world than any other group of wild animals or plants because they are easily seen and recognised. Their colours, songs and movements fascinate, and their ways of life provide an interest for a growing number of serious bird-watchers. The books reviewed here reflect some of the different levels and areas of interest in birds: one relates facts about the adaptations of birds to their habitats in various parts of the world; and five others deal with more discrete groups. None of the books is highly technical.

I tend to be suspicious of large 'coffee-table' books which consist of glossy photographs or paintings often supporting a poor text. In *Birds and their World* (Hamlyn: London and New York, £2.95), however, John Andrews has written one of the best texts that I have found in such surroundings. Lucidly written, and full of facts about the relationship of birds to their habitat in the major biomes of the world, the book describes structural and functional adaptations to the particular characteristics of the biomes. A single chapter on migration seems out of place. As one might expect, since it is a Hamlyn publication, three-quarters of the book are taken up by colour photographs. These are of ex-

cellent quality generally, but a few have been enlarged far too much. At £3.95 it is good value for the general bird-watcher.

More expensive and less value for money is *Penguins: Past and Present, Here and There* (Yale University: New Haven and London, £6) by George Gaylord Simpson, Professor of Geosciences at the University of Arizona. Simpson became interested in penguins when, in the course of field research, he discovered a collection of fossil penguin bones. Despairing of finding any palaeo-ornithologist to work on the collection, he embarked on the task himself. In his book, therefore, the most interesting and worthwhile chapter is written round his own discoveries. Since that study he has visited many penguin colonies but has not been able to undertake further research. The remainder of this book therefore relies on previously published literature, of which he gives a limited bibliography. It is a pleasant enough "informal account" to quote the book jacket. The black-and-white photographs have not reproduced too well and the colour photographs are amateurish.

Very different is the contribution of the author in two books on raptors—*Birds of Prey: Their Biology and Ecology* (Hamlyn: London and New York, £4.50) and *Eagles of the World* (David and Charles: Newton Abbot and London, £4.95). Nominally they are put out by two different publishers but the page design, type and binding are

extraordinarily similar. In both books Leslie Brown reviews what is known about various aspects of the life of raptors—classification and distribution, habitats, way of life, way of hunting, breeding biology, ecology—and adds much original material. There is some overlap between the books, and in *Birds of Prey*, the author inevitably writes in greater detail on eagles. In both books he points out areas in which research is needed and could be easily undertaken. The books are rather discursive in style but interesting in an anecdotal sort of way. Both books are illustrated by explicit diagrams and line drawings; black-and-white photographs only in *Eagles of the World*, but both colour and black-and-white photographs in *Birds of Prey*. Each is provided with a fairly large "select" bibliography, very useful appendices summarising a variety of data. Both are good value for money.

Winter Birds (Michael Joseph: London, £5.75) by Malcolm Ogilvie concentrates on those birds that live and breed within the Arctic Circle. Aimed at readership on both sides of the Atlantic, Malcolm Ogilvie begins his book with a chapter describing the nature and extent of the Arctic followed by another on the adaptations by birds to Arctic conditions. Four chapters follow on waterfowl, sea, shore and land birds found in the Arctic, and the book finishes with a chapter on the need for conservation in the Arctic. Generally the text maintains a high level of interest but I

Above illustration: *The Archangel Gabriel, part of a miniature from Syria or Egypt (14th century, British Museum, London). Taken from Islam and the Arab World, reviewed on page 596.*

wondered if giving each bird species found in the Arctic was the best way of dealing with this group of birds. Some accounts are interesting, particularly those on waterfowl, which are the author's speciality; and on waders, such as knot, on which much research has recently been carried out. But some other sections are mere repetitions of textbook material. Chapters describing and comparing the characteristics of individuals of the group in the Arctic might have been far more readable and have provided an opportunity for more discussion. Maps and photographs are useful additions to the text as is the up-to-date bibliography. The book is well produced—recommended for Arctic enthusiasts.

Tony Soper's book *Everyday Birds* (David and Charles: Newton Abbot and London, £2.95)—a very popular account of the lives of nine very common birds—will please children and the less discriminating adult bird lover. Much of the text is very simple, factual and moves at a great pace, which is possibly why he makes the occasional careless statement such as "birds are controllers of insects" and "birds have a great sense of adventure". This book will be lapped up by a large market who will also enjoy Robert Gillmor's excellent drawings. □

Peter Conder has recently retired as Director of the UK Royal Society for the Protection of Birds.

Spirit of Nature needs rekindling

OVER the past ten years, the study of animal social behaviour has undergone a dramatic change. Gone are the days when animals were held to do things 'for the good of the species' or for the benefit of their group if it meant that they themselves suffered in the process. Altruism—in the sense of behaviours which benefit the reproductive success of other unrelated individuals at the expense of an animal or its relatives—is contrary to the Darwinian theory of natural selection. Selfishness and exploitation are the rule. So harsh a master is natural selection that it is not even the individual that benefits in the long run, but his genes. The individual animal has a finite lifetime, but his genes, in the bodies of his offspring, and in the offspring of his brothers and sisters or other relatives live on. Hence any genetic propensity to benefit relatives will be increased because the relatives will also be likely to have the same propensity. This idea of 'kin selection' has been fully developed by W. D. Hamilton.

In view of this shift of thought ('revolution' is too strong a word: it is more a realisation of what was implied all along by the theory of natural selection), it is disappointing to find that so many recent popular books still perpetuate the fallacy that the species is the unit of selection and seem unaware of recent developments in the field of evolutionary biology. This is particularly apparent in *The Mating Game* (Elsevier-Phaidon: Oxford, £4.50) by Robert Burton, a lavishly illustrated account of animal courtship and reproduction. The photography is most impressive, but the text is full of such statements as (p10) "the individual is unimportant and survives solely for the benefit of the whole", and (p8) "the

function of sex is thus to ensure that animal populations are composed of a variety of individuals". The function of sex is one of the most hotly debated issues among evolutionists precisely because 'good of the population' arguments have been found to be inadequate. It may certainly be advantageous for the population as a whole to be variable, but the problem is that sexual reproduction involves producing individuals that contain only half the genes of each parent, an apparently enormous cost genetically, which asexually reproducing individuals would not have. The work of R. L. Trivers has made us take a new look at animal courtship and pair bonding. Animal family life is seen as a world of exploitation of one sex by the other, of cheating and of strategies involving cooperation only when this is selfishly the best thing to do. There is no mention of this aspect in the book, nor any of the genetic relationships between the members of a social insect colony, which is crucial to an understanding of their curious reproductive system.

Something of the same fallacy is apparent in John Napier's book *Monkeys without Tails* (BBC: London, £5.25), which on p33 states that "the whole life style of animals is a preparation for ensuring the continuity of their species" and that "animals that do not reproduce are biologically irrelevant". On the contrary, kin selection theory has shown that non-reproducing individuals may be genetically very important. This book, although a very interesting account of primate biology does not quite live up to its subtitle—*A Giraffe's-eye View of the Evolution and Life History of Man and the Chimpanzee*. The idea is an appealing one—to look down on man from a great height as a rather ordinary primate—but the book is nevertheless rather noticeably anthropocentric. Man is placed at the top of the primate

"staircase", with the "great divide" separating us from our primate relatives. There is a lot of useful information in this book, however, and it is very readable.

The Secret Life of Animals (Weidenfeld and Nicolson: London, £8.95) by Lorus and Margery Milne and Franklin Russell also insists that (p112) "whatever the behaviour is that best suits the survival of the species, occurs", but is redeemed by some really superb photography. The book really does succeed in conveying a sense of awe and wonder about animal life, which *The Amazing World of Animals* (Thomas Nelson: London, £4.50) edited and with a foreword by Sir Peter Scott also sets out to do. This book contains some good photographs, and chapters on different animal groups by various authors.

The Classification of Animals (White Lion: London, New York, Sidney and Toronto, £3.75) by Richard Freeman is a most useful illustrated summary of the classification of living animals, with examples, a clear indication of the numbers of species in each group covered, and a brief but informative description. It is concise, but at the same time satisfyingly comprehensive—the basic taxonomic information needed by a zoologist in a few pages.

The Language of Smell (Routledge and Kegan Paul: London and Boston, Massachusetts, £3.95), also by Robert Burton, is a summary of how animals smell and the uses to which they put their sense of smell, at a fairly elementary level. The recent evidence that shows that von Frisch has been right all along in claiming that the dances of honeybees transmit directional and distance information, is apparently unknown to the author. One is therefore, mistakenly given the impression that von Frisch is now generally considered to have been wrong and that bees rely on smell alone.

It is a relief to turn to *Bird Life: An Introduction to the World of Birds* (Elsevier-Phaidon: Oxford, £5.95), with a text by Christopher Perrins. Here at least the basic evolutionary framework is sound and the current thought on social behaviour, mating, and so on, is simply and well explained. The book covers in a readable way various aspects of bird life, such as feeding, social behaviour, migration and so on. It is clear, non-technical and has numerous coloured drawings by Ad Cameron, which although expert and lifelike, might perhaps be thought a little monotonous as the sole source of illustration.

Marian Dawkins is a Departmental Demonstrator in Animal Behaviour in the Department of Zoology, University of Oxford, UK.

Capturing the secrets of Nature

NATURAL HISTORY must still be the subject most likely to kindle an interest in science in the tinder-dry mind of a young child. The problem is how to tend the flame so that the interest becomes a passion. When I was a child the process included Nature walks, listening to BBC radio's *Nature Parliament* and *How Things Began* and, of course, books. Now, streets ahead of anything else, there is film.

Film allows us and our children, at home and at school, to view every intimate detail of the erstwhile secrets of Nature. No longer do we wonder what goes on in the darkness of a woodpecker's nest nor contemplate the riddle of the landing of a fly on the ceiling. Given a steady diet of fantastic film, can the jading palate of today's child still be tempted by a book on Natural History? To judge by the masses of such books on the market the answer must be yes, or at least the adults who buy the books must believe so. For a book to be successful, however, it must surely attempt to match rather than ignore the dramatic qualities that the moving film has brought us. Only one of three series currently available really does that.

The success of the *A Closer Look At . . .* series (Hamish Hamilton: London, £1.50 each) rests heavily on the illustrations and the consistently good, sometimes inspired, layout. There are no photographs in these books. Instead the pages are generously supplied with full colour drawings which, at their best (for example, in . . . *Elephants* and . . . *Apes*) are vivid double-page spreads capturing a group of animals in mid-action. Each double page also has a few hundred words of text addressed to a particular topic, which vary from book to book but which generally start with evolution or geography and close with the prospects for . . . Information in the main part of the book is, however, centred either on species or behaviour. With such a limited amount of text the choice of topics or facts has inevitably been slightly arbitrary but a certain balance has nevertheless been maintained in each volume.

The publishers of the series make no claim as to the age group for which it is suited. The books certainly succeed as picture books for the six year old—particularly the more gory offerings, such as the death by leopard of an Australopithecine boy (. . . *Prehistoric Mammals*) or the spider-killing wasp (. . . *Bees and Wasps*) and I am sure that the text would carry the series up to the start of the teens. There are occasional oddities: the concept of

Emperor tamarin (marmoset monkey)

ridiculous and ridiculous birds may be worth a page in the . . . *Birds* book but surely one could do without the terms themselves. And failings: the quality of the illustrations in . . . *Arctic Lands*. But overall these are excellent and reasonably priced books.

The second series, to which *How Insects Live* (Elsevier-Phaidon: Oxford, £4.50) is the latest addition, is clearly, if not explicitly, aimed at the teenager. But it would have to be an already committed one who actually benefited from the books. That, to my mind, is the failing of the series. In general design the volumes resemble a 'coffee-table' production both in size and in the abundance of handsome colour photographs. But the design belies the text which is by turns dull, didactic or of the "just-fancy-that" variety. Where

exactly did the editor expect to find readers whose attention would be captured by Haeckel's dictum that "ontogeny repeats phylogeny" (*How Fishes Live*, £3.95) or by the correlation between the breeding behaviour of ring doves and the weights of their oviduct and crop contents (*How Birds Live*, £3.95)? Perhaps the bookish student, aged 15 or over, will appreciate these volumes; otherwise, buy them only if you cannot resist the photographs.

The *Nature's Way* series (G. Whizard/André Deutsch: London, £1.75 each) is to my mind an even greater failure. The origin of this series is the Oxford Scientific Film Unit which is rightly renowned for its Natural History films. These books (*Bees and Honey*, *Life and Times of the Stickleback*, *Butterfly Cycle*) are clearly spin-off material. Each consists of about five pages of simple text followed by about twenty full page coloured photographs. The text is unexceptional, and the photographs are generally fine, but I was dissatisfied, perhaps through frustration, at the inevitable failure to translate action into stills photography. Once through these books was enough for me, and would, I suspect be enough for children. Not enough, however, to be able to recommend them as worth buying.

I have surprised myself by coming down heavily in favour of the series of books that relies on artistic rather than photographic illustrations. If you want the 'real' thing I can only say stick to television or, far better, head for the country.

Peter Newmark

Peter Newmark is Biological Manuscripts Editor of Nature.

Nature on the seashore

ALTHOUGH books about the seashore might seem more relevant as a preparation for summer holidays, they may nevertheless make acceptable Christmas presents for scientists specialising in other subjects, laymen or the generation still at school or university. Two books have appeared in the shops during 1976 and it is interesting to compare them with some other books written over the last 27 years which are still available.

Taking the new books first, we have *The Hamlyn Guide to the Seashore and Shallow Seas of Britain and Europe* by A. C. Campbell (Hamlyn: London and New York, £2.25). This book is bound in durable paper that might withstand rain or seawater to a limited extent during shore collecting. The illustrations, by James Campbell, all in colour, are well above the average for this type of book. After a very brief

introduction on types of seashore, tides and collecting, the non-biologist is thrown in at the deep end with two pages of "key" which cover the entire plant and animal kingdom. The reader must then find his or her way to the right phylum where a brief description of the phylum is followed by a list of species divided into classes and families. It is essential for the reader to find the plant or animal by its picture. Once this has been achieved the genus, species, authority, popular name, size, brief description, habitat and distribution are given. At the end of the book there is a glossary, bibliography and index. For identifying shore life, this book may well be the best available on the market and at its modest price is strongly recommended for the amateur shore collector.

The second new book, *A Field Guide to the Mediterranean Seashore* by W. Luther and K. Fiedler, translated and edited by P. J. Miller (Collins: London, £4.95) is a hardback with a cover of what seems to be

On Science and Surgery

160 pp. £4. Student edition £1.50

at the University Press, 22 George Square
Edinburgh

Circle No. 13 on Reader Enquiry Form.

waterproof material. After a somewhat longer introduction on habitats, each phylum is described in turn and its representatives given by class, order and family. Although each species is briefly described with Latin and popular name, size and habitat, the illustrations are much poorer than the Hamlyn book; many are only black-and-white, and those in colour are given against a coloured background that seems to provide an unnecessary and sometimes confusing contrast. The book ends with a section on collecting, marine aquaria, a bibliography and index. There is no glossary or general introductory key so the non-biologist, although he might find the book a useful companion on a Mediterranean holiday, may have difficulty in tracking down a specimen.

Collins' Pocket Guide to the Seashore by J. H. Barrett and C. M. Yonge (Collins: London, £3.95) is still being reprinted as the 1958 edition in hardback. Covering both plants and animals, it is divided into phyla and the main subgroups (down to species) to be identified by a proper key. Having at last arrived at the species, the Latin and popular names are given, with a fairly full description of anatomy, habitat and distribution. This is a more difficult book for the amateur (or

professional) to use; not all species are illustrated; and the illustrations (partly black-and-white, and partly coloured plates of good quality) are placed together near the centre of the book and not with the species description. There is a bibliography, index and a useful introduction. According to the introduction the book is aimed at amateur naturalists, who will probably find more species described than in the Hamlyn book but will certainly require more patience in locating their specimens from 'first principles'.

In very different style is *The Seas* by F. S. Russell and C. M. Yonge (Warne: London and New York, £6.95). First published in 1928 and reviewed in its revised form by Sir Cyril Lucas (*Nature*, 258, 36, 1975) we find a book divided into 17 well-illustrated chapters. This is not a book for identification or reference; it is a collection of essays in non-technical language on various aspects of marine biology. The book is readable, and would provide the amateur with a good general picture of all aspects of the sea and sixth-formers or first-year university students with worthwhile background information.

Equally well-produced is *The Sea Shore* by C. M. Yonge (Collins: London, £6.50 hardback, £0.95 paper-covers). This is one of the celebrated New Naturalist Series originally published in 1949, reprinted last in 1971

and still available. It is at a similar technical level to *The Seas* but the 19 chapters are restricted to the shore areas, with a more detailed description of subjects like Life in Rock Pools, Zonation on Rocky Shores, and Life on Sandy Shores, Mud or in Estuaries. The book is beautifully illustrated and highly readable and will take a rightful place with others of the New Naturalist Series on any bookshelf.

Finally, *Fishes of the Sea* by J. N. and G. Lythgoe (Blandford: London, £3.90 hardback). Although described as a coloured photographic guide to the fishes of the British Isles, Northern Europe and the Mediterranean, it consists also of an introduction to fish anatomy as well as descriptions and line drawings of each species. There are many coloured and black-and-white underwater photographs placed together at the centre of the book which might be used by SCUBA divers for identifying fish in their natural surroundings. The book is thus of restricted value to the shore collector and non-diver, but would be a worthwhile addition to the luggage of amateur divers holidaying next summer either in the UK or on the continent.

J. H. S. Blaxter

Dr Blaxter is Senior Principal Scientific Officer at the Dunstaffnage Marine Research Laboratory of the Scottish Marine Biological Association at Oban, Argyll, Scotland.

Enthusiasm for shell collecting

The Shell Collector's Guide: An Introduction to the World of Shells. By S. P. Dance. Pp. 192. (David and Charles: Newton Abbot and London, August 1976). £4.95.

SHELL COLLECTING or conchology is among the oldest known intellectual leisure activities. The fascination of "shells that speak seven seas" (one of the many apposite quotations from unlikely sources—this one is from Dylan Thomas) is evidenced by shell jewellery from archaeological sites about thirty thousand years old. More recently, excavations at Pompeii have unearthed shell collections, evidence of the interest in conchology that this book will doubtless help to perpetuate. Peter Dance has written an enthusiastic, honest, technically expert and enjoyable book about a semi-scientific hobby which can bring great contentment (and occasional heady excitement) to young and old alike.

Many naturalists have tried to put into words something of the fascination of conchology. As a hobby, it is all

things to all men. It appeals to the outdoor person who wants to punctuate his rambles by rustic searches; to the SCUBA diver and his less adventurous wading or dredging comrades; to the young who marvel at the exquisite geometry of shells; to the old who take satisfaction from their patient systematic accumulations over the decades and from postal exchanges with enthusiasts all over the world; to those of an artistic persuasion who love the beauty of shells; to scientists who yearn to make order from chaos and enjoy arranging, naming and cataloguing their collections. In short, first and foremost, conchology is FUN. It can, and occasionally does, lead to advances in the scientific study of the Mollusca, and can bring rich intellectual rewards to those who embrace it. It can also be physically pleasant to handle shells, although not everyone would agree with Mr Dance that touching cowrie shells (for example) provides a "decidedly sensual tactile satisfaction".

This book will tell you everything you need to know to begin searching for, cataloguing, preserving and displaying a shell collection. It tells you about shell clubs, shell shows, valuing,

exchanging and buying shells. Fascinating sections of the book deal with shell frauds, and with the commercial exploitation of the rarest shells. Did you know, for example, that prices of certain shells at auctions have now topped the \$4,000 mark?

One of the best features of the book is the high quality of the illustrations, with a splendid series of photographs by Ian Cameron and well chosen and beautifully executed drawings by Annabel Milne. The standard of production of this book is uniformly excellent and it is pleasant to note that it was printed and assembled entirely in Britain.

Why then is my brow furrowed? Simply because I share with many other professional zoologists a frightful vision of a world in which all the molluscs are on display in skilfully designed cabinets, and the seas, lakes, marshes, streams and woods are malacologically empty. If anyone doubts that this is more than an irrational nightmare, he should ask himself how many butterflies he has seen in Britain during recent years; have lepidopterists any share of the blame for their dearth?

The author offers no balm for my anxieties about the possible predatory effects of indiscriminate shell collecting. He advocates searching for living molluscs (so that they may be killed for their shells) rather than taking empty shells from the beach deposits, and describes in detail various unpleasant methods of torturing the animals out of their shells after capture. He describes one method which is so hideous that he says he never himself has practised it (why then lend it currency?).

About wholesale commercial conchology (reef raping, as an Australian described it) he lamely says he does not propose to take sides or to argue the rights and wrongs. About the legitimate and calmly voiced fears of naturalists about the future of the mollusc world, wanting to keep the word 'conservation' before the shell collector, Mr Dance says only this: "For some mysterious reason, the scientific world appears to think that it has almost a divine right to Nature's products". This is unfair. Speaking personally, I do not want to conserve molluscs simply so that I and others in my laboratory can catch and experiment on them; I want to conserve them so that my grandchildren (and Mr Dance's) can see and admire them. I hate to feel that I may be living in the last generation of mollusc enthusiasts.

T. E. Thompson

T. E. Thompson is a Reader in Zoology at the University of Bristol, and President of the Malacological Society of London, UK.

Artistic impetus for scientific observation

Bright Wings of Summer: Watching Butterflies. By D. G. Measures. Pp. 160. (Cassell: London, October 1976.) £5.

THIS book is the work of an artist. David Measures goes out to his disused railway line in Nottinghamshire and draws and paints, describing what he sees in the butterfly world at various times of the year and in different weather conditions. He reproduces his notes and his delightful sketches, full of movement and swift life, and in the past twelve years he has collected a great deal of first-hand information on topics such as scents, courtship, mating, egg-laying and territorial boundaries in a unique way which is not to be found in the standard books.

The object is to set out the life histories and behaviour of butterflies in a way which will stimulate readers to become interested in Natural History and to make and record their own accurate observations. The unfinished paintings and the roughly written notes show how in practice conclusions are arrived at.

The book is divided into three parts. In "The Beginnings" he describes his own life history. He started with a general love of nature and then, because of his preoccupation with colour, concentrated on butterflies. "There is nothing so brilliant, or as changing and shifting as the iridescence and the pigmented colour of the butterfly's wing".

Part 2 gives the results of his observations, and lastly, "You and

Butterflies" gives practical advice as to how to follow in his footsteps.

The lesson for the pure scientist is that each insect is an individual and that, when one classifies, something is lost—although for a physician-reviewer accustomed to looking after patients this does not come as a surprise.

On the other hand, art must not be allowed to get away with it completely, and with more scientific knowledge the author's observations could have been more productively channelled. What precisely happens to our red admirals in the autumn? Burnet moths are resistant to cyanide, and cinnabar caterpillars feed on the poisonous ragwort—what are the predators of these insects? Do the black and white forms of the peppered moth actually settle on appropriate backgrounds? Similarly, where in nature do caterpillars with brown and green chrysalids actually pupate?—the colour and texture of the site are of great interest. The extent of bat predation at dusk also needs investigating.

Other criticisms are that there should be more emphasis on the difference between camouflage and warning coloration (p. 72) and surely the plate opposite page 100 is not the small heath. In general, however, the photographs are superb.

The book can be strongly recommended for nature lovers with artistic inclinations, but there is no reason why imagination and science should not be brought closer. E. B. Ford's *Butterflies* (which is recommended for further reading) exemplifies what I mean.

Cyril A. Clarke

Sir Cyril Clarke is a general physician with an interest in genetics which stemmed from breeding butterflies. He is President of the Royal College of Physicians.

Jumbo the elephant

Jumbo. By W. P. Jolly. Pp. 173. (Constable: London, September 1976.) £3.95.

BORN into a matriarchal society in the wild bush of Africa, captured and transported to the Jardin des Plantes in Paris, the 4-year-old elephant was then exchanged for a rhinoceros, a piece of trading which almost certainly saved him from a stewy end in the seige of Paris of 1871. A more tranquil period followed with little to do to earn an almost limitless supply of buns other than carry wide-eyed children on rides round London Zoo.

Jumbo, for this was his name, thrived in London and grew apace. Jumbo was no more than a name of African origin but one which was to come into everyday use and be synony-

mous with largeness. The period of adolescence ended in pain of two kinds, the physical pain from abscesses which formed following the breaking of both tusks and the pain and puzzlement of puberty which seems to afflict the male elephant in the constraining environment of captivity.

The physical pain was assuaged by the surgeon's lance but the latter required very pragmatic action, if the embarrassment of an Elephant amok in the Zoo was to be avoided, and resulted in Jumbo's sale to Mr Barnum, the great American showman. The bill of sale was easy; the delivery of a reluctant elephant was, however, fraught with difficulties, difficulties that resulted in enormous publicity which promoted the forthcoming arrival to the American people and increased the anguish of the British public at the loss of their animal hero.

How little times have changed. Good organisation and one suspects the right kind of word from the animal's keeper, who could not but fail to profit from the increasing fame of his charge, and despite attempts for an injunction against the sale, Jumbo was loaded on the *Assyrian Monarch* and after an uneventful journey arrived in New York in April 1882. There then followed the razmataz of the American circus life which continued until Jumbo's death following a collision which Special Freight Train number 151 just over 3 years after his arrival in the New World.

The author draws from many sources to relate the tale of Jumbo's life and times. He links together the extracts from that period in a way which at times I found rather tedious, phrases like "yester year's politicians prize from China" to describe Mr Ted Heath's contribution of Pandas to London Zoo is but one example. But this could not spoil a fascinating story of a most unusual animal. The book is a must for all Jumbophiles.

R. J. Wheeler

Mr Wheeler is Director of the Royal Zoological Society of Scotland.

The Bethnal Green Museum of Childhood, London, UK, has mounted a special exhibition (November 25, 1976-January 23, 1977) of material related to the story of Jumbo. The exhibition also includes a wide variety of examples of the elephant in art, and contains toy elephants and a selection of photographs and drawings from children's books.

Jumbo with admirers at London Zoo

Snapshots in the field

Field Photography: Beginning and Advanced Techniques. By Alfred A. Blaker. Pp. xxi+451. (Freeman: San Francisco and Reading, 1976.) \$19.95; £12.60.

THE camera is used by scientists to observe, collect and record data and to help communicate the results to fellow workers. Most government scientists can call on the services of professional photographers who produce photographs that are technically superb. But even these fortunate scientists, as well as ones without such facilities available, need to take photographs themselves as the opportunity presents itself, and this is especially true for those whose work takes them into the field.

The scientist who takes his own photographs has the advantage that he knows exactly what he wishes to portray. The result is, however, too often spoilt and rendered unfit for publication by lack of the proper equipment for the job, or the lack of rudimentary technical knowledge. One of the primary aims of *Field Photography* is to provide sufficient information for the scientist to overcome these difficulties. All too often articles and books on modern photography are

either technically too complex for this purpose, or consist merely of a series of photographs joined together with the minimum of words or explanation. *Field Photography* is noteworthy for its balance of text and illustrations. It can be readily understood by the beginner and yet contains much that is of interest and help to the photographer with some knowledge or one who has experience in some other branch of photography.

The steps needed to perform a certain operation are always given clearly and at length. Sufficient information is always conveyed for the reader to understand the reason for the processes involved, but the theory underlying the operation is usually only given at length when needed to enhance the practical performance. And the author does not dwell unnecessarily on the chemical or physical aspects of photography.

The book is divided into three major parts. In the first, the reader is skillfully piloted through the maze of photographic equipment and materials that are available, including the basic types of cameras, lenses, extension tubes, bellows, filters, light meters, flash meters, tripods, film and printing paper. The particular advantages and disadvantages of various items of equipment are clearly discussed: even veteran photographers should occasionally pause to reflect

whether the system they have adopted or evolved is really the most suitable for the job at hand, or whether it merely reflects ingrained habit.

In the second part of the book general photographic techniques are reviewed, emphasis being placed on: picture composition; exposure, including the use of light meters and electronic flash techniques; the purpose and use of filters, especially as they relate to scientific recording in the field and their use in infrared and ultraviolet photography; and darkroom procedures.

The third part is specially concerned with field photography techniques and is in many ways the most valuable. There can be few photographers who could not learn something from it. The subjects discussed include: climatic problems and protection of equipment; high resolution techniques, including camera handling, film processing and printing; macro-photography, including the use of supplementary lenses, teleconverters, extension tubes, and lens reversal; use of telephoto and wide angle lenses; techniques of stereophotography; and use of fill-in flash. The few pages in this section that are devoted to the correct disposal of photographic waste material and the avoidance of damage to the environment would seem unnecessary to the scientist who habitually works in the field.

The book is well produced and the clarity of presentation is enhanced by some excellent and purposeful black-and-white and colour illustrations, and many line drawings, figures and tables. Included with it is a booklet in which many of the mathematical formulae and tables used to calculate lens apertures and shutter speeds are reproduced, so the photographer can have readily available information with him in the field.

Field Photography is good value, especially if it succeeds in its object of instructing the scientist who buys it to take photographs outdoors efficiently and economically.

John B. Free

John Free is an entomologist at Rothamsted Experimental Station, Harpenden, UK, and a professional natural history photographer.

Volcanoes

Volcanoes. By Peter Francis. Pp. 368. (Penguin: Harmondsworth, Middlesex, July 1976.) £1.50. *Volcanoes*. By A. and L. Rittmann. Pp. 128. (Orbis: London, 1976). £4.95.

"THERE are many books on the market called *Volcanoes* . . . so why write yet another?" Thus begins Peter Francis in his addition to the *Pelican Original* series. And he has his own answers to the problem. Volcanology, he explains, is a fast-moving discipline, both conceptually and spatially. Studies that once encompassed little more than explicit phenomena on the surface of the globe now extend from the Earth's core to the far side of Mercury. Then there are the hidden implications of volcanoes. On the surface a volcano may be just a volcano, but an eruption has far reaching ramifications often ignored by other authors. And finally, most treatises on volcanoes are textbooks.

Peter Francis wanted to write one free of "academic pretensions" for a less than specialist readership, and his attempt at meeting that objective is an unqualified success. Here is a gem of a book; from the outset his knowledgeable fascination with volcanoes and all they represent shines through. Gifted with a lucid and breezy style he carries his narrative across every major facet of volcanology, penetrating surfaces just deeply enough to provide sufficient foothold for the next conceptual step. Nobody will get lost along the way, and few will want to abandon the journey.

The book proceeds logically, condensing a mass of detail as it does so. It starts clearly with a description of

volcanic distribution—the Mid-Atlantic Ridge, the Pacific Ring of Fire, and so on. This, of course, is merely plate tectonics from another angle, but it provides the author with the opportunity of introducing the fundamental geophysics of volcanology and all that that entails—from basic mantle chemistry and convection cells, through oceanic magnetic anomalies, to the Low Velocity Zone.

The author proceeds to paint a vivid picture of what volcanoes are and what they do. The scene is set with a straightforward descriptive chapter on three diverse "classic eruptions"—Vesuvius in AD 79, Krakatoa in 1883, and Mont Pelée in 1902—which, with the graphic inclusion of asides on the plight of unfortunate victims, provides a clear idea of the varied ways in which volcanic action can manifest itself.

But it is the following chapter which perhaps best highlights the author's skill as a scientific narrator. Dealing with the classification of eruptions, again everything is there—central and fissure eruptions, basaltic flood eruptions, Vulcanian and Strombolian eruptions, Hawaiian eruptions, and so on. The obvious pitfalls are confusion and complexity; but Francis does not trip up, making his central point clearly and concisely.

Lava types (a few words here on mineral chemistry and petrology), pyroclastic falls and flows, volcanic morphology and volcanic evolution are then considered, and by the end of chapter 7 the story could have been complete on many counts. But Francis is scarcely more than half way through. As he says bluntly: "a volcanic eruption does not take place in an environmental vacuum". So we get *hlaups* and *jökullhlaups*, volcanic pollution, *tsunamis*, climatic effects, volcanoes and the origin of life, and even vol-

canoes as money spinners—ores, geothermal power, and the like. A chapter on volcanic prediction and mitigation (La Soufrière is topical), a journey out to Mercury (by way of the Moon and its history, and Mars), and at last the text reaches its breathless end.

Peter Francis' *Volcanoes*—361 pages crammed with information—is thoroughly comprehensive and crystal clear. Written to inform non-specialists, it does so with panache.

By comparison, *Volcanoes* by Alfred and Loredana Rittman is a strange offering, the more so in view of the senior author's standing in his field. As the dust cover proclaims, he is indeed a "world authority"—an ex-President of the International Association of Volcanology, and founder of the International Institute for Research into Volcanology.

With that in mind his latest contribution emerges as a sadly disappointing work. It really belongs to that peculiar breed known as the 'coffee-table' book. Without doubt, the 120-odd full-colour pictures are breathtaking—of the type that beg to be looked at time after time. But the real difference between this book and Francis' (and given the similarity of textual approach the comparison is valid), is that whereas Francis writes to invest his photographs with life, the Rittmanns' present a relatively abtuse and somewhat superfluous text that is far outdazzled by the pictures. So if you have a coffee table and a penchant for Kodachrome catastrophe, the Rittmanns' *Volcanoes* is the book for you; if not, spend your money on the other option.

Allan Piper

Allan Piper is Assistant Editor of The Oilman.

Astronomy for the amateur

STARS and planets, galaxies and space are topics of tremendous interest to many non-scientific members of the general public. In fact astronomy is second only to natural history in the layman's top ten of scientific subjects, and this is amply reflected in the plethora of popular astronomy books published every year. These books are difficult to classify but the seven under review fall into four basic groups, the encyclopaedic all-you-want-to-know about astronomy from A to Z; the picturesque, where a large collection of glossy photographs are interspersed

by brief descriptive texts; the armchair tomes for the fireside astronomer; and the 'get-up-and-go' books which encourage you to actually go outside and gaze, hopefully with wonder, at the heavens.

First let us consider the two encyclopaedias. These ABCs of astronomy are ideal for people who want to look up simple astronomical facts and who want quick answers to questions without having to study a lengthy chapter in a book. A. Weigert and H. Zimmermann's *Concise Encyclopaedia of Astronomy* (Adam Hilger: Bristol, £9) is a revised and expanded second edition of the original *ABC der Astronomie* first published in 1967. There are over 500 pages of facts, many illustrations, sixteen plates and a fine collection of star maps going down to

fifth magnitude. This book is for the advanced amateur and is also an excellent reference book for first-year university students. Simple mathematical relationships between quantities are effectively used and the tabulation of stellar and planetary data is first rate.

The Illustrated Encyclopaedia of Astronomy and Space (Macmillan: London, £7.95), edited by Ian Ridpath, contains contributions from twelve or more people from diverse astronomical backgrounds. This encyclopaedia tries to bring together astronomy and space science, and amongst the 1,000 entries are some very informative tables giving details of such space programs as Apollo, Surveyor, Soyuz, Discoverer, Salyut and Skylab. The book is equally divided between space and astronomy—for example, the planet Saturn is allocated as many column inches as the Saturn rocket. In fact I think the book goes too far into space—Frank Borman the Apollo 8 mission commander is allocated eleven lines, and the fundamental astronomical concept of black-body radiation is afforded scant reference in the section on spectroscopy. It is well illustrated but is much more simplistic than the work by Weigert and Zimmermann. Ridpath's book reads more like an astronomical *Guinness Book of Records* and seems to be aimed at people in their early teens.

The Southern Universe (Macmillan: London, Melbourne and Sidney, £4.95) by Lennard Bickel is so lavishly illustrated that it can almost take its place with those other 'coffee-table' books designed just to be flipped through to look at the pictures. This is, however, a bit unfair as the text is worth reading especially if you can overcome your dislike of journalistic flamboyance:

"The Clouds of Magellan are portals to outer space. Their location—50,000 parsecs above the South Pole—is our threshold to the greater universe, an arena so vast it is better described as—the cosmos. This is the great empyrean of the heavens, the region of supreme creation where scientific astronomy is joined by cosmology and modern physics in the search for understanding of the true Beginning."

Yeuk! There again it might be just the thing for the kiddies. Interestingly the book is written by an Australian, with the cooperation of many Australian astronomers and with a strong emphasis on the southern sky, a refreshing change from the usual bias towards the northern hemisphere.

Isaac Asimov writes for the armchair astronomer, and his book, *Eyes on the Universe: A History of the Telescope* (Andre Deutsch: London, £4.95), sets out to tell two stories. First, a fascinating account of the technological

achievement that developed the telescope from the first Heath-Robinson contrivances of the pioneer astronomers to the giant optical and radio telescopes of today. And second a narrative of mankind's supreme intellectual adventure as he reaches out and tries to comprehend the nature, scope and origin of the Universe. The book succeeds admirably and tells its rather complex tale, without the use of mathematics, in a clear and succinct way. A perfect example of good scientific popularisation.

Astronomy for the Amateur (Macmillan: London, £2.95) is a short, well illustrated introduction to astronomy. John Gribbin has written for those people "who have noticed the fascinating lights in the sky and would like to know a little more about them". It is a guide for people embarking on astronomy as a hobby, tries hard to keep alight the fascination and wonder of this exciting science, and succeeds very well.

Moving outside we come to James Muirden's *Astronomy with Binoculars* (Faber and Faber: London, £4.95 cloth, £2.75 papercover), a new and revised edition of the book first published in 1963. Astronomy is an intimidating science, many newcomers imagining that astronomical research can only be carried out in big observatories. Muirden tells us all to get outside on the frosty winter nights and train our binoculars on the sky. There are chapters on the observation of the Sun (needless to say *not* with binoculars), Moon, planets, comets, meteors aurorae and stars. In each case the author describes in detail what we should be looking for and prefaces these descriptions by a brief introduc-

tion to the physical conditions prevailing on the object. This book conveys all the excitement and challenge of astronomy, and the owner of a pair of binoculars will find the book worth every penny of its cost.

Finally, I come to *Stars and Space 77* (Independent Newspapers: London, £1) a ninety-six page, magazine-style paperback, which firstly describes the night sky for every month of the coming year—giving well drawn and very clear star maps plus details of planetary positions and lists of interesting stars to look out for. The second half is given over to reviews of the major advances and discoveries during the past year. These three- to four-page articles cover such subjects as exploding black holes, X-ray satellites, other planetary systems, the solar influence on the Earth's weather, comet West, and Viking. The author list reads like a Who's Who in Astronomy, and Ian Ridpath, again editor, must be congratulated on an excellent publication—fantastic value for money at only £1. Heaven help the sales of Patrick Moore's *Yearbook of Astronomy*.

Looking at all these books the question to ask is: "Which, assuming you are a young astronomer or a recent addition to the realms of amateur astronomers, would you like to find in your stocking on Christmas Day". The choice is enormous, but for me the answer is simple. James Muirden's *Astronomy with Binoculars*, wins hands down, with Ridpath's *Stars and Space 77* also making a superb and cheap stocking filler.

David W. Hughes

David W. Hughes is a Lecturer in the Department of Physics at the University of Sheffield, UK.

Ecology of human skin

The Life That Lives on Man. By Michael Andrews. Pp. 183. (Faber and Faber: London, 1976.) £4.95.

TELEVISION has brought many aspects of science vividly to huge audiences, and the programme *The Life That Lives on Man* did this most successfully. It gave an accurate picture of the human skin, and had shown—with shots of dust pouring out of our underclothes—how we shed some ten thousand million tiny skin scales a day, losing in a year a weight of over a pound from our tissues. It had also shown photomicrographs of the bacteria and the various arthropods which live on and in the skin, and described the diseases some parasites may cause. There were accounts of the research

on these parasites, and reconstructions of some of the unusual experiments (including those in which man was the victim) which contributed to this research. It was obvious to the viewer that an immense amount of work had gone into preparing the script, and in taking and editing all the photographic material. It seemed a pity that so much effort should produce so little permanent result, for even the most attentive viewer retained only a fraction of the information which illuminated his screen when the programme was presented on television.

It was therefore an excellent idea when Michael Andrews decided to write "the book of the film". In it he has been able to include much that his research revealed which could not be shown on television because of pressure on time or because not all aspects of the subject are equally photogenic. Mr Andrews has produced a fascinating

Catching lice, by Bartolommeo Pinelli (Rome, 1781-1835)

Photo: Mansell Collection

book, scientifically accurate and yet free from irritating jargon. It should appeal to the non-scientist, and yet has something to teach the specialist, including the dermatologist and the parasitologist.

Although the text is enlivened with historical anecdotes and literary allusions, with poems about the parasites and epigrams at the expense of the parasitised, the book is fundamentally an exercise in ecology—the ecology of the human skin. We learn that the millions of bacteria which inhabit it are normally in balance, although many are potentially the cause of serious disease. When man does not interfere by washing too frequently, or applying potent chemicals to neutralise natural body odours (not BO, which is generally a pathological symptom) and to prevent natural sweating, the various micro-organisms can usually co-exist in mutual harmony. Dangerous pathogens are somehow prevented from increasing to damaging numbers. It is clear that many bacteria and other micro-organisms are beneficial and not harmful to their hosts, a situation recently described in Bernard Dixon's book *Invisible Allies*. The skin is seen to behave much like other, larger, ecosystems.

Stability may, however, be upset in all ecosystems, and the skin is no exception. Dangerous bacteria do sometimes get out of control, perhaps because man, with his unguents and cosmetics, has upset the balance. It must also be admitted that it is difficult

to determine in what ways most arthropod parasites contribute to the well-being of the host which supports them. Lice suck our blood, irritate our skin so that we scratch and admit pathogenic bacteria to make the wounds fester; and the insects also infect us with dangerous rickettsiae which cause epidemic typhus. Fleas bite and inoculate us with the plague bacillus—the cause of the deadly "Black Death" of the Middle Ages. These infestations

Coffee-table medicine

Triumphs of Medicine. By H. Keen and J. Jarrett. Pp.193. (Paul Elek: London and New Hampshire, 1976). £12.50.

LAVISHLY illustrated books on art, history, architecture and travel have proved so successful that from time to time a publisher attempts to apply the same technique to a scientific theme. The size (30×23 cm) of this Paul Elek production puts it firmly into the 'coffee-table' class, but it is far from a typical example—except in its high price.

Professor Harry Keen and Dr John Jarrett set out to describe the main achievements of medical science as seen against a historical background. Their 17 expert contributors have served them well in identifying the important advances made in the control of infections, in anaesthesia, and in surgery and many new techniques of

seem to be singularly one-sided affairs. The reason may be that the arthropods are, for the most part, recent additions to the fauna of the human skin. The germs they carry may be better adapted to mammals other than man. Both vectors and micro-organisms may not yet have had time to develop anything like a symbiotic relationship with man.

There is in fact some suggestion that such relationships may be evolving. Although the arthropod parasites may not benefit man they do seem, in the majority of cases, after an initial rather heavy infestation, to decrease in numbers to produce a balanced, rather small population which does not cause intolerable discomfort. Thus the majority of lousy children, including those with long-term chronic infestations, have only about a dozen lice on their heads. Most patients with chronic scabies support only a similar number of *Sarcoptes* mites. Perhaps the idea, prevalent among Victorian slum dwellers, that a few lice on a child's head was a sign of health may have some foundation. Perhaps low and relatively harmless populations of ectoparasites prevent other and more dangerous invaders from damaging our skin. The ecological ideas put forward by Michael Andrews in this excellent book may stimulate scientists to investigate these problems anew.

Kenneth Mellanby

Although Professor Mellanby was at one time a Reader in Medical Entomology, he has become better known for his work at the Monks Wood Experimental Station, Huntingdon, UK, and for his success in conveying the complexities of science to a wider audience.

diagnosis and treatment. They have also explained the growth in our understanding of the structure and biochemistry of the body in health and disease. Although some chapters, such as Professor Roy Calne's account of the kidney and of organ transplantation are models of clarity, others—though technically competent—are fogged by patches of the impenetrable jargon characteristic of so much medical writing. Perhaps because the editors realised that too many of the contributions were too detailed for a non-specialist readership they included a glossary of technical terms; but even that assumes a considerable scientific vocabulary.

Books of this kind stand or fall on their appeal to the eye. A high standard has been set by designers such as George Rainbird (responsible for successes such as Douglas Botting's biography *Humboldt and the Cosmos*), whose formula depends on the faultless reproduction of large numbers of plates of exceptional beauty, many of

them in colour. In contrast, the reader browsing through *Triumphs of Medicine* finds no colour; and though every page has a picture and many are full plates, few are really eye-catching. Many of the full-page illustrations are taken from X-ray films; again, their technical quality is excellent, but few non-medical readers will find them informative. Virtuoso examples of the radiologist's skills, such as a film showing exactly where blood is leaking from an artery into the intestine, mean little to someone who has never seen an angiogram before. The same criticism may be made of the photomicrographs; without explanation they are meaningless to the non-medical eye and they have little visual impact.

There is an exciting story to be told in the growth of medical expertise as part of the twentieth century explosion of scientific knowledge, but the telling must be adapted to the audience. Here the target is far from clear, for a collection of intellectually demanding essays has been confused and interrupted by a haphazard mixture of technical illustrations, historic cartoons, line drawings, portraits, and journalistic photographs. The packaging is not consistent with the content, and in consequence the result will please neither the specialist reader nor the curious layman.

Tony Smith

Tony Smith is Assistant Editor of the British Medical Journal and Medical Correspondent of The Times.

Islamic masterwork

Islam and the Arab World. Edited by Bernard Lewis. Pp. 360. (Knopf in association with American Heritage: New York, 1976.) \$35.00. (UK edition (*The World of Islam*) published by Thames and Hudson: London, 1976. £12.50.)

THE publication of this first American edition of *Islam and the Arab World* is truly an occasion for celebration.

MAGNUS PYKE BUTTER SIDE UP!

or The Delights of Science

Does bread and butter fall more often butter side down or up? Did Popeye really owe his vigour to can after can of spinach? Ask Magnus Pyke an apparently silly question and he will give an eminently sensible answer that reveals the inner workings of science. Following up many of the trails started during ITV's very popular series *Don't Ask Me* and heading off on many new ones Dr Pyke has gathered a rich crop of scientific eccentricities.

Drawings by ffolkes
8 pages of photographs
£3.95

**JOHN
MURRAY**

Furthermore, the celebrants need not be Arabic or Islamic scholars alone, for the volume is sure to be appreciated by the complete spectrum of professionals, from artists to zoologists. At a casual glance, this profusely and beautifully illustrated book might appear to be a classier version of a typical multi-colour 'coffee-table' book, which are more often valued for their role as icebreakers in a conversation, rather than for their intrinsic value. That would indeed be an incorrect impression because in the (effectively) fifteen chapters of the book, the reader is gently but carefully guided through topics such as the explosion of Islam in the Arabian peninsula and beyond, the art and architecture of the vast Dār al-Islām, ranging from Andalusia to Bengal, its literature, natural sciences, music and a bird's-eye view of its up-to-date political history. Each chapter is written by unquestionable authorities on their subjects, seemingly handpicked by Professor Bernard Lewis not only for their scholarship but also for their ability to communicate with the lay public and, what is more important, for their unusual sense of balance. In fact, there are perhaps only one or two chapters which occasionally show lapses in this latter mentioned quality.

The title of the book could be slightly misleading in that a potential reader may not realise the existence of whole chapters in the book dealing with Muslim Spain, Iran from the Safavids onwards, the Ottoman empire, and last but not least, Muslim India. Thus, in the strict definition of the Arabist, the present volume deals with the whole of Islamic culture (or "Islamicate" culture as the late Marshall Hodgson would have said) and not just Arabic civilisation. The corollary of that is the book's involvement with the whole of Dār al-Islām since the Prophet's birth.

Musician with oblique flute, Persian album painting, 1560-70

Courtesy Sotheby's, London, UK

The chapter entitled "The Scientific Enterprise" deserves special notice because of the sparkling characteristics of this long essay. It is well-known to students of Islamic science that other than the articles in *Encyclopedia of Islam* (incomplete second edition) or the *Legacy of Islam* (1974), there is not even a satisfactory monograph on the subject of Islamic science. Obviously, Professor Sabra's article in twelve pages (even if they are quarto-size pages) does not remove this inadequacy, but it goes a long way towards initiating an intelligent and non-partisan discussion about the paradox of the coexistence of rationalists (falāsifa) and the orthodox religious thinkers (Ahl as-Sunnah).

Although the book is a masterwork, I would like to slip in a few minor criticisms here: the dust cover is too garish and projects too narrowly martial an image for such a world culture; the excellent chapter on music does not mention a word about Hindustani music; and for a confirmed epicure it is distressing to find not only a lack of mention of Turkish cuisine which vies with the French and Chinese as a primary world cuisine but that even the word 'food' is never mentioned. Perhaps the coffee-table culturists would at least have liked to know the origin of the word 'coffee'!

Subir K. Banerjee

Subir Banerjee is Professor in the Department of Geology and Geophysics at the University of Minnesota, Minneapolis, Minnesota, and has recently been appointed an Adjunct Professor in the Program of Middle Eastern and Islamic Studies at that University.

nature*December 16, 1976*

A few months' relief, but what then?

So, at the eleventh hour, a way has been found for the Science Research Council (SRC) to pay its international subscriptions, notably to CERN, without thereby bankrupting all its other activities. It isn't clear as yet that the hat which had embarrassingly to be passed round all manner of scientific establishments for donations to the cause will be passed back intact, but there is hope that the modest sum that was found therein will eventually get back to the kindly oceanographers, invertebrate virologists and so on who did their bit. But at the risk of boring our readers even more—and we promise to say nothing further on the subject in 1976—there are still some unanswered questions about the future of international subscriptions in times of inflation and a sliding exchange rate.

The somewhat disturbing truth about the resolution of the problem for this financial year (to March 31, 1977) is that it has been possible only by some dexterity in shuffling funds and reinterpreting rule books at the Department of Education and Science (DES) and the Treasury. There had always been a feeling around that the cash-limits problem could be circumvented somehow, and so it turned out. Some money (about £2.5 million) which had been earmarked for university purposes in the form of an operational reserve was early on seen to be spare and the Treasury had pointed this sum at the SRC. But the real breakthrough came when some very careful reading of the rulebooks, and, one suspects, some very slight reinterpretation of them, showed that a sum of £1.6 million previously thought to be the responsibility of the research councils was found to be chargeable to other departments involved in commissioning research in council establishments. Not £1.6 million was saved that way, but double it!

If this means a somewhat relaxed Christmas for all concerned, it doesn't necessarily mean good news for the

financial year 1977–78. In the next few weeks the results of Britain's widely leaked commitment to the International Monetary Fund to reduce public spending in exchange for a large loan are bound to trickle through the Whitehall machine. It would be foolish to think that in some way science can be buffered from these cuts, either in the sectoral departments with a science and technology constituent or through the Department of Education and Science. All of which means that there are not only bound to be several uneasy months as decisions are made on whether staff levels are to be maintained or whether the cuts are to be passed on to sub-contractors, university departments and the like; it also means that the monolithic international subscriptions, not open to little bits of trimming here and there, are bound to become more exposed, occupying, as they will, a growing fraction of SRC's budget. And the idea of strict cash limits, which has been at the root of this year's difficulties, is likely to be around for years to come judging by the general enthusiasm in Whitehall for them.

Thus, although this year's patching-up operation is welcome indeed, the lack of any sort of systematic resolution of the problems brought on by variable exchange rates will leave us with a perennial headache, unless the pound starts to move the other way. The waste of time, the stirring up of animosities, the internal conflict that followed this year's difficulties are not things that ought to become an annual feature of the life of practitioners of big science. It still seems to us most desirable that within the near future a mechanism will be found by which international subscriptions are not jeopardised by currency fluctuations. Other countries manage it—surely if DES contains people clever enough to convert to a £1.6 million bill into a £1.6 million IOU, it contains people clever enough to devise means of saving themselves the bother in future years. □

The breeder reactor: a fossil fuel viewpoint

David Merrick considers what economic and technical factors would make the fast breeder reactor a viable option

THE concept of the fast breeder reactor is elegant and simple: to generate electricity and, at the same time, to produce additional fuel from the uranium discarded by the existing thermal reactor system. Without the breeder reactor, it seems likely that the role of nuclear energy will begin to be constrained by the price and availability of uranium at about the turn of the century. There is, however, no consensus on the desirable, or even possible, contribution of breeder reactors to future energy supplies. Foremost among the uncertainties discussed in the current debate are the questions of safety and environmental impact. Assuming concern in these areas can be satisfactorily and economically resolved, there still remain questions on the technical and economic limitations of the use of breeder reactors.

Performance of the breeder system

In making the case for the breeder reactor, the most commonly quoted index of performance is that 30% to 60% of the energy available in the uranium fuel can be liberated, compared with about 1% in most thermal reactors. The exact value of the efficiency depends on the plutonium losses in reprocessing, the 60% figure being valid only if these can be limited to 2%.

In addition to approximately 4 tonnes of plutonium in the core, a 1 MW breeder reactor contains about 50 tonnes of depleted uranium in the core and blanket. This is converted by the reactor to plutonium (and other elements) and typically, a further 50 tonnes of depleted uranium are required as replacement during a lifetime's operation. A single breeder reactor will, therefore, utilise only 15% to 30% of the uranium required for its operation, if the initial charge is included.

The uranium inventory can be considered as a form of storage and remains useful provided there is a continuing programme of breeder reactor construction. If, however, an expanding programme of breeder capacity is planned, a further constraint, the availability of fissile material for the reactor core, is encountered. Although it would be technically possible to use highly

enriched uranium for this purpose, to do so would be costly, and the reactor performance, although improving slowly during the lifetime of the plant, would not initially be in the 'breeding' regime¹. For these reasons the design of breeder reactors, and scenarios for their introduction (for example the United Kingdom Atomic Energy Authority's 1974-75 evidence to the Royal Commission on Environmental Pollution²), concentrate on the use of plutonium as the fissile material.

It is expected that the Liquid Metal Fast Breeder Reactor (LMFBR) will breed 20%-25% more plutonium than is required as fuel. This excess plutonium can be used as inventory for further breeder reactors. A crucial parameter affecting the strategy for the introduction of breeder reactors is the doubling time, that is, the time taken for a breeder reactor to produce sufficient plutonium to provide the initial fuel charge for another similar reactor. The doubling time depends not only on the breeding gain of the reactor itself, but also on the delay time and losses in reprocessing the partially burned fuel. At the present state of reactor and reprocessing technology, the doubling time would be more than 50 years³, although this is expected to be cut to a period in the range 25 to 40 years for commercial reactor systems (at a 70% load factor). As neither the reactor nor the reprocessing plant are likely to be demonstrated on a commercial scale for several years, it seems prudent to assume a mid-range value of, say, 33 years for planning purposes.

It is claimed that further reductions in the doubling time could be obtained by using carbide instead of oxide fuel, or a gas-cooled reactor instead of the present liquid metal designs. However, even the achievement of a 33-year doubling time in an acceptable commercial system will entail a substantial development programme, and whether sufficient incentive would then remain to embark on further such programmes is not clear.

At the beginning of a programme of breeder reactor construction, the plutonium required for the reactor core would be obtained as a by-product of the thermal reactor programme. In most situations, the available stocks of plutonium would be rapidly exhausted, and the rate of construction of breeder

reactors would then be limited by the rate at which plutonium becomes available from existing thermal and breeder reactors. In the UK, for example, stocks of separated plutonium would, at present, enable 1 GW of breeder capacity to be built⁴. This should rise to about 7 GW in 1985.

Whether the breeder programme can ever become independent of the thermal reactor programme depends on the growth rate of the nuclear electricity system, and the doubling time. At a doubling time of 33 years, plutonium production from the breeder reactor system can only sustain a growth rate of around 3% per annum. For the growth rate of the nuclear electricity system to be greater than 3% per annum, it is necessary to construct both thermal and breeder reactors.

In this situation, the efficiency with which uranium is utilised by the overall system of breeder and supporting thermal reactors is considerably lower than the value of 60% claimed for the breeder reactor alone. This is illustrated in Fig. 1, which shows the uranium utilisation for the system of breeder (LMFBR) and supporting thermal reactors (PWR) at various growth rates. Also shown, for comparison, is the uranium utilisation if the CANDU thermal reactor, with plutonium recycle, were to be used. This system performs better than the LMFBR/PWR system at growth rates above about 5% per annum.

If, therefore, a rapid build-up of nuclear capacity were desirable, the LMFBR/PWR system would, during the period of growth, offer a relatively small improvement in uranium utilisation over the PWR, and little or no improvement over the CANDU system. Only if the projected plutonium doubling time of commercial breeder reactor systems were to be substantially reduced could a high growth rate in breeder capacity be achieved, but there is no evidence at present that this would be technically or economically possible.

Growth of the breeder system

Besides limiting the overall efficiency of uranium utilisation in the nuclear reactor system, the availability of plutonium for the cores of breeder reactors

Table 1 Estimated uranium import requirements 2000-2020 AD

Growth rate (% per annum)	LWR + LMFBR	LWR +Pu recycle	CANDU +Pu recycle
1	39,000	105,000	51,000
3	76,000	214,000	103,000
5	220,000	433,000	208,000

also acts as a constraint on the rate at which breeder capacity can be introduced. This can be illustrated by considering an idealised situation in which the commissioning of new power stations precisely matches the steadily growing level of demand. The maximum rate of introduction of breeder reactors is shown in Fig. 2 if, at year zero, new power station construction is suddenly switched from fossil fuel to nuclear.

At annual growth rates in electricity demand below 3%, breeder reactors can eventually account for all nuclear power generation, although to achieve this takes at least 50 years. At higher growth rates, the ultimate contribution of breeders is limited, as discussed above.

For a given electrical output thermal reactors generally produce plutonium at least as quickly as breeders. If the introduction of breeders is delayed, plutonium stocks can, therefore, be built up, enabling breeder capacity to increase rapidly once the breeder programme begins. Even a delay of 30 years does not significantly affect the time required for the breeder to reach the maximum possible contribution, as shown in Fig. 2.

Forecasts of the rate of growth of breeder reactor capacity and the impact of uranium imports to the UK are complicated by the present over-capacity of power stations and the plutonium stocks from existing stations. Approximate estimates of uranium requirements in the first 20 years of next century are given in Table 1, assuming that an early decision to go ahead with a demonstration-scale breeder reactor is made. This would enable the first orders for commercial plants to be made by the middle/late 1980s for commissioning in 1995.

The introduction of breeder reactors will, on this timescale, only reduce uranium consumption to just under half of the requirements of a nuclear programme based on the PWR alone and will show little advantage over the CANDU thermal reactor. The choice of thermal reactor system can, therefore, have a similar impact on uranium requirements to the breeder on this timescale, and cannot be divorced from the decision to pursue breeder technology. The sixty-fold improvement in uranium utilisation frequency claimed for the breeder will not be realised for the system as a whole until well into next century. Although the medium-term savings will be worthwhile provided uranium prices are high, breeder technology cannot ensure a secure, indigenous supply of energy, effectively insulating the UK from the expense of high cost uranium, for more than half a century.

Economics of breeder reactor systems

Although it has been claimed that the capital cost of fast breeder power stations need not be greater than that of thermal stations, it now seems likely that, even if there are no major technical difficulties, the cost will be at least 25% more than that of a PWR. In order to be economically viable, this additional capital investment must be paid for by the lower fuel costs. At present, the cost of uranium ore accounts for less than 10% of the total generation cost so that, other factors being equal, a substantial increase in the price of uranium would be necessary to justify the extra capital cost of a breeder reactor.

This is confirmed by a more detailed analysis, which shows that the approximate cost of uranium ore needed for a breeder to produce electricity as cheaply as a thermal reactor is directly proportional to the additional capital cost of the breeder. (The plutonium produced by the breeder and thermal reactors is credited with its value as a supplementary fuel in thermal reactors, although in the case of the breeder this credit is more than offset—at a 10% discount rate—by the cost of the initial charge of plutonium.) Although this analysis is necessarily approximate, such a relationship means that the FBR is unlikely to give visible economic benefits until uranium prices have increased to \$100–\$200 per pound of U_3O_8 . This represents an increase in real terms of three to six times.

The rate at which uranium prices will move upwards depends on the future growth of world nuclear capacity and reserves and discoveries of high grade uranium ores. Neither of these can be estimated with any certainty and no consensus of opinion exists on the earliest date at which this consideration would be decisive in favour of the breeder. The UKAEA anticipates that uranium prices will increase to \$100–\$200 a pound when all the high grade ores are committed to existing nuclear programmes in the 1990s, and conclude that breeder capacity should be built up as quickly as possible. The Central Electricity Generating Board (CEGB), however, takes the view that the main justification for the FBR is in reducing requirements for uranium in the long term, as resources may be limited, rather than on economic grounds.

In order for nuclear energy to remain competitive for base load power generation duty at uranium prices in the range \$100 to \$200 a pound, fossil fuel prices would have to rise by between 50% and 100% relative to power station construction costs. Although, in the UK, power station coal now costs about 2½ times as much as it did three years ago (an increase even allowing

Fig. 1 Uranium utilisation in a steadily expanding system.

Fig. 2 Rate of growth of breeder capacity in an idealised system assuming various annual growth rates for electricity demand. For the 3% annual growth curve, the effects of delaying introduction of the fast breeder by 10, 20 and 30 years are shown by dashed lines.

for inflation), power station construction costs have risen by a similar amount over the same period, leaving the relativities in power generation costs not greatly different.

There is clearly a possibility that the increased cost of nuclear power generation brought about by high uranium prices will either reduce the competitiveness of nuclear electricity compared with other forms of energy or, should the price of the alternatives also increase, inhibit economic growth and consequently energy demand. In either case, the assumption of a continued high rate of growth in nuclear capacity after high grade uranium ores are exhausted appears open to question.

Fossil fuels

The justification for the breeder is essentially long term. No clear economic advantage is likely until uranium prices have risen three to six times above their present level. Furthermore, the contribution of a breeder/LWR system to reducing uranium requirements is unlikely to exceed that of an

efficient thermal reactor system until well into the next century.

If demand continues to grow so that it becomes impracticable to rely on thermal reactors, fossil fuels, and renewable resources for power generation, the breeder reactor would have an important contribution to make. It is against this scenario that the development of breeder technology could be considered a valuable assurance of adequate electricity supplies.

After the turn of the century, it is expected that crude oil and natural gas production will begin to decline. This, because of the unique advantages of fossil fuels, will encourage substitution either directly or indirectly, by coal. For that to occur most efficiently, new technologies for the combustion of coal and its conversion into substitute hydrocarbon fuels are required.

The development of coal conversion processes and breeder technology have certain similarities. In both cases, the construction of demonstration scale plants will soon be required. The earliest times by which each technology need be applied in the UK are similar, although both could, if required, be introduced before they become economic in order to forestall sudden increases in energy prices. Once the technology has been demonstrated,

however, the rate of commercial exploitation of coal conversion processes is not limited as for the fast breeder reactor, and a significant impact on energy supplies should be possible in a comparatively short period of time. Furthermore, the UK is already in a strong position on coal technology and the export potential of coal conversion processes should be no less than that of breeder technology.

The size of the relative contributions of breeder technology and coal conversion processes depends on whether electricity will continue to penetrate the energy market as prices increase. It is probable that substitute fuels from coal will be most effective competitors for nuclear electricity in the heating market. The estimated capital cost per unit of energy output of, for example, a plant to convert coal to substitute natural gas is about one third that of a nuclear power station, and the thermal efficiency is approximately double. Furthermore, the low load factors associated with the heating demand do not affect the economics of coal conversion as much as electricity generation. The use of nuclear energy for other than electricity generation does not look attractive at present, and would require considerable technical problems to be solved.

In conclusion, breeder reactors are capable of making a substantial contribution to energy supplies by using the uranium rejected from the thermal reactor programme. The availability of plutonium is likely to limit the rate at which breeder reactors can be built for several decades. If a vigorous development programme enabled breeder reactors to be introduced commercially by the 1990s, even although they would probably not be economic by this date, they would be unable to insulate the UK effectively from the need for expensive uranium imports until well into next century. The need to develop and demonstrate breeder technology can therefore be compared with the development of other medium-term energy options. Coal conversion processes, in particular, will be required to play a vital role in this timescale and merit no less attention and priority than breeder technology. □

I thank Mr L. Grainger, National Coal Board Member for Science, for guidance and encouragement, and the NCB for help with the preparation of this article. The views expressed are, however, my own and not necessarily those of the NCB.

Dolphin dissonance

Colin Norman reports from Washington on the threat that tuna fishing poses for dolphins

IN the past 15 years, between 5 and 6 million dolphins are believed to have drowned in the nets of tuna fishermen. The slaughter of these highly intelligent, friendly mammals has sparked one of the most bitter and complex conservation battles ever waged in the United States. A number of environmental groups, backed to some extent by the federal government, are fighting to protect the animals, while the tuna industry, according to its spokesmen, is fighting for its own survival. The battle is now focused on regulations, due to take effect in January, which conservationists say are vitally needed to protect the dolphin schools, but which the tuna industry claims will put the United States tuna fleet out of business.

The dolphin owes its plight to the fact that, for unexplained reasons, some species frequently swim with yellowfin tuna—a type of tuna which is in high demand and which fetches the highest prices. Because the air-breathing dolphins swim on the surface, they have for decades provided

tuna fishermen with a convenient guide to the location of schools of yellowfin. Until the late 1950s, tuna fishing was mostly done by hook and line, and the dolphins lost nothing by showing fishermen the way to yellowfin schools. But a technological innovation in the industry rapidly changed all that.

The innovation was the development of a massive net, called a purse seine, which tuna fishermen spread around dolphin schools and then draw in to land the yellowfin beneath the dolphins. It is a very effective way to catch tuna, but the problem is that dolphins frequently become entangled in the nets and, when they can't get to the surface to breathe, they drown. During the 1960s, an average of about 400,000 dolphins a year were dying in tuna nets; since they have no commercial value, they were thrown overboard.

Because the dolphin schools play a valuable role in leading tuna boats to yellowfin, it is in the fishermen's interest to try to preserve the animals by reducing the slaughter. They began to experiment with various manoeuvres

and changes to the nets in the 1960s, but the killing continued virtually unabated until 1972. At that point, Congress stepped in.

Public concern

Public concern over the killing of marine mammals had been aroused by the plight of many species of whales, which had been hunted virtually to extinction, and the needless slaughter of dolphins by tuna fishermen consequently became an emotionally charged issue in the early 1970s. Congress responded to the concern by passing the Marine Mammal Protection Act (MMPA) in 1972.

A compromise between the argument that the tuna industry would be wiped out by a total ban on the killing of dolphins, and the need to protect the animals, the act essentially gave the industry a two-year grace period. By October 1974, the act said, the killing of dolphins by purse seiners must be reduced to "insignificant levels approaching zero".

Congress had been led to believe that such a requirement could be met. During testimony before a House committee in 1971, Joe Medina, a tuna boat captain, reported that trials with a modified purse seine had reduced the kill of dolphin in a 'set' to insignificant amounts. "This new net has been a

salvation for us, and I think we have the problem licked", he said. Unfortunately, his optimism was unjustified.

According to a study by a panel of experts last July, the total number of dolphin killed by all tuna fishermen, including non-US operators, dropped from 348,000 in 1972 to 217,000 in 1973, and it dipped again to 120,000 in 1974. But it increased last year, reaching 181,000. Clearly, the requirements of the MMPA were not being met and the Commerce Department, which was supposed to be enforcing the Act, wasn't doing much about it.

In December 1975, the Commerce Department moved. It announced that it would permit fishing of yellowfin associated with dolphins in 1976, provided estimates made in the first quarter of the year indicated that the total 1976 dolphin kill would be less than 70% of the 1975 kill. The announcement raised a storm of protest from environmentalists, who went to court to try to force sterner measures on the industry. On May 11, 1976, Judge Richey in the Federal court in Washington DC set the tuna industry back on its heels.

In an unprecedented decision which minced few words, Judge Richey ruled that the Commerce Department's proposal violated the MMPA. The act, he said, places the interests of marine mammals above the economic interests of the tuna industry, and he ruled that all killing of dolphins by US fishermen must cease by the end of the month. The prohibition, he said, should stay in effect until the Department of Commerce can determine "that such killing is not to the disadvantage" of dolphin stocks. The decision was upheld by the Court of Appeals, but a delay in implementing it was granted until January 1, 1977.

In the meantime, the Department of Commerce came up with some new regulations for 1976. It said that tuna fishermen could continue to fish for yellowfin associated with dolphins until the total dolphin kill for the year reached 78,000. That level was reached on October 19, and after the tuna industry had exhausted its legal appeals, all killing of dolphin by US fishermen supposedly stopped in mid-November.

Conference of experts

In July, the department called a conference of experts in marine resources to try to ascertain present population levels of various dolphin species. The panel was asked to determine whether any species is in danger of falling below the so-called optimum sustainable population (OSP) level, and to try to estimate the impact on each species of various levels of kill next year.

Tuna fishermen at work

The conferees reported that the spotted dolphin population—the species most often caught in tuna nets—has been reduced to about 64% of its original level since the introduction of the purse seine. The eastern spinner dolphin—one of a number of types of dolphin which twist in the air when they jump out of the water—was reckoned to be in the worst shape; it has declined to nearly 50% of its original population level. The conferees said that a 50% decline in the population of any species would put that species below its OSP level.

One of the conferees, Dr William Aron, Director of the Office of Ecology and Environmental Conservation in the National Oceanic And Atmospheric Administration, testified last month that "while I do not contend that any of the (dolphin) stocks under consideration are presently endangered or threatened with extinction, past history indicates that a cautious approach is warranted". Aron argued that the unhappy experience with whale populations "suggests that a reduction in cetacean populations to much under half their original stock size may present a significant threat to survival of those populations".

On the basis of the conference report, the Department of Commerce issued in October regulations for 1977 which are designed to ensure that the number of animals of each species of dolphin will increase or at least remain within their OSP levels, an objective consistent with Judge Ritchie's ruling. The department essentially took the maximum kill levels which would still allow numbers of each species to increase, estimated the likely kill by non-US fleets, and set quotas for US tuna fishermen accordingly. The proposed regulations sent the tuna industry running for its lawyers and, if the industry's figures are accurate,

fighting for its survival. The industry is appealing the regulations in a lengthy public hearing.

The regulations would limit the total dolphin kill next year to some 61,400 animals, of which US fishermen would be able to kill some 29,900. In particular, the regulations would prohibit US tuna boats from setting their nets around dolphin schools containing any spinner dolphin.

Welcomes and worries

The proposed regulations have been welcomed by environmentalists. Christine Stevens, secretary of the Society for Animal Protective Legislation, calls the proposed quotas "a tremendous step in the right direction", though she points out that they are still some way from the MMPA's goal of insignificant mortality. And environmental groups, led by William Butler of the Environmental Defense Fund, have generally argued in favour of the proposals in the public hearings.

Nevertheless, the regulations will clearly have a severe economic impact on the industry. Even the Commerce Department's environmental impact statement on the proposals notes that the effect "may be severe". Unless the industry can reduce the number of dolphins killed per ton of tuna, the impact statement suggests that the US catch will drop by about one-third, which "could lead to the collapse of the US fleet if exvessel prices do not rise proportionately".

Industry spokesmen are now less restrained in their views. Frank Alverson, vice-president of Living Marine Resources, a research organisation supported by the tuna industry, claims that the total prohibition on netting spinner dolphin alone will "automatically deny the US fleet access to 68,000 tons of fish", valued at about \$45 million. That figure represents the

amount of yellowfin caught this year in association with spinner dolphin.

Environmentalists tend to take some of the industry's dire warnings with a pinch of salt, however. In particular, Butler has pointed out that tuna taken in association with dolphin actually account for a relatively small fraction of the total tuna catch. The Japanese tuna fleet, which is one of the largest producers, does not fish on dolphin at all. And a study done last year by Gordon Broadhead, president of Living Marine Resources, found that nearly 60% of the US tuna catch in 1975 consisted of skipjack or yellowfin caught when swimming in schools separate from dolphins. It is therefore argued that the US fleet will simply turn its attention to those other sources of tuna. Industry spokesmen counter, however, that such a switch would send the US fleet into areas already heavily fished by foreign vessels, and they argue that next year's skipjack catch is likely, on the basis of past trends, to be below average.

The industry therefore claims that the regulations will cause heavy losses among tuna boat operators, many of whom are already on the verge of bankruptcy. The industry is therefore fighting the regulations on several fronts. One line of attack is to challenge the estimated population levels, particularly that for the eastern spinner dolphin. Another is to argue that the regulations will penalise US tuna fishermen while allowing foreign fleets to fish at will.

Troublesome problem

The problem with non-US fleets could be troublesome. There is no mechanism available to reduce dolphin kills internationally, and thus, in meeting the

court requirement that there should be no detrimental impact on dolphin stocks, the Department of Commerce had to focus its attention entirely on the US fleet. The upshot is that if the regulations are put into effect, US fishermen will be denied access to tuna which could be available to other fleets and if the effect is to increase foreign fishing on dolphin, the net result could be disastrous.

The Department of Commerce estimates that the kill rate among foreign vessels fishing on dolphin is more than twice as high as the kill rate of US vessels. Thus, if foreign vessels move in on yellowfin schools denied to US vessels, the net effect could be to increase dolphin mortality.

There is, however, a way in which the United States government could exert leverage to prevent such a situation. The US is now the world's chief importer of tuna—domestic supply accounts of only about half US consumption. The MMPA gives the government power to insist that imported tuna is caught in accord with US regulations, and if such a requirement is enforced, a large switch in the operation of foreign fleets may be avoided.

The industry is also arguing that it has made considerable progress in reducing the mortality of dolphins per ton of tuna, and that if it is allowed to continue fishing, further progress can be anticipated. For years, tuna vessels have used a procedure known as backing down, which essentially causes part of the net to drop below the surface, enabling most of the dolphin to swim free. Another improvement, the so-called Medina panel, consists of a strip of fine mesh around the top of the net to reduce the chance that dolphins

will become entangled in the webbing, and other gear alterations are under test. According to Alverson, the tuna fleet has so far spent about \$1.7 million in gear modifications to reduce dolphin mortality.

Nevertheless, there is good reason to believe that the industry has not been as generous in funding research as it likes to suggest. It was not until December 1975, three years after Congress passed the MMPA, that the industry established a research body to study methods to reduce the dolphin kill. Known as the Porpoise Rescue Foundation, it is being funded only to the tune of \$250,000 a year. The federal government is funding at least three times that amount of research.

Though most of the studies are concentrating on gear modifications, two projects are focusing on different approaches. One, which is being tested on captive tuna in Hawaii, consists of trying to separate the tuna from dolphins by chemical attractants, and the other, which is much further from field testing, attempts to do the same thing by acoustical means.

Whatever the success of those methods in reducing dolphin mortality, it is clear that the industry will not be able to comply next year with the MMPA's goal of near zero levels. Consequently, the Department of Commerce will be hard put to justify relaxing its proposed quotas. The result, forecasts Lewis Regenstein of the Fund for Animals, is that the industry "will be breaking down the doors of Congress" to seek legislative relief. It will be a tough fight, but if the tuna fishermen get their way, environmentalists are already talking about the possibility of a boycott of tuna. □

White hope or white elephant?

What is happening at the European Molecular Biology Laboratory? **Walter Gratzer** looks at its first annual report

COMING at so bleak a juncture for European science, the 1975 annual report of the European Molecular Biology Laboratory (EMBL) strikes a brave and heartening note. To readers in Britain, who have seen the traditional patrons and defenders of molecular biology, the Research Councils, cringing under the lash first of Rothschild and now of the Treasury, a refreshing feature of the report is that it makes no effort to propitiate the avenging taxpayer: not once in its 50 pages is there even a token mention of heart disease, tooth decay or lower back pain.

The laboratory was conceived at the height of what Stent has called the Golden Age of molecular biology, when it was bliss to be alive, and its ten-year gestation period has seen many changes. A document published in 1966, when the project was still in the womb of time, asserted that for the undertaking to be worthwhile a multidisciplinary structure would be essential, and that all major areas of molecular biology would have to be represented; so grand a design, it suggested, would be outside the compass of any single European national institution. The laboratory would be a

major centre of scientific excellence and a nucleus for postdoctoral training, and it would nourish the university departments of Europe with a supply of the kind of young men then appearing in such profusion in America—minted at Harvard or MIT, and finished to a high radiance at NIH or Stanford. In this way Europe would regain the initiative that had by then passed to the Americans. The EMBL therefore must be large (150 scientists, 15–20 of them permanent). In contrast to CERN its object would not be to provide plant too expensive for the individual member countries to set up; in biology, the report affirmed, the plant consisted of interacting groups of scientists with outstanding and complementary talents.

Well, circumstances, as they say, alter cases and as Thurber observed, there is no safety in numbers or in anything else. The projected size and

scope appear both now to be considerably shrunk, and the report emphasises throughout the development of technical facilities sufficiently advanced to attract or generate interesting research projects. The laboratory is of course still in an early stage of growth, and is indeed a tenant in another institute in Heidelberg, pending the completion of its new building. Its Director is Sir John Kendrew, who has carried the entire project since its inception, and has recruited a predominantly young and active staff, but none of the ageing mandarins of the European molecular biology establishment.

Trendy blend

There is a trendy blend of research topics, with a strong cellular emphasis. The new investor, assembling his first portfolio, is of course best placed to take account of the steady rise in neurones and cell motility futures for example, without the pain of first getting out of slumping commodities, such as ribosomes or bacteriophage. The laboratory, then, has groups working on membranes in viruses and mitochondria, a division of biological structure (for the present confined to the development of methods in scanning electron microscopy), and a large division of cell biology, in which are subsumed four varied areas of research. There is a group working on chromatin and another on the control of chromosomal activity, using as the experimental material the giant chromosomes of insect salivary glands. There is a programme on control of morphogenesis, involving the isolation and study of peptide hormones that regulate differentiation in *Hydra*. An imaginative departure, not perhaps without the danger of creating an island within the laboratory, is the inclusion of a programme under Dr N. Strausfeld, concerned with the neuro-anatomy of the visual system of insects.

In addition to the activities in its Heidelberg laboratory, the EMBL has absorbed two major existing projects which in fact seem now to constitute its most substantial undertakings. These are facilities for X-ray diffraction with high-intensity radiation from a synchrotron and for neutron diffraction, and are based respectively at Hamburg and at Grenoble. These outstations are operated as a service to European workers, and are being furnished with supporting laboratories for preparative and related work. The neutron source has already been put to widespread use, and (at an estimated cost, as I am told, of \$1 per scattered neutron) provides an example of an installation that could nowadays scarcely be run on any but an international basis. The Grenoble outstation is directed by a member of the

laboratory staff, Dr A. Miller, and is evidently a thriving concern.

The synchrotron X-ray source in Hamburg was developed and delivered into the care of the EMBL by Professor Ken Holmes, and its potential is undeniably enormous. Some spectacular exercises have already been performed, and a number of diffraction photographs of truly remarkable quality from insect muscle have made the rounds of the conferences, and have apparently sent the adrenalin coursing through the veins of fibre crystallographers. By following the evolution of a single reflection on addition of ADP to a muscle fibre, it has even proved possible to obtain a titration curve, and from it a binding constant. By making use of the larger flux from a storage ring, also in Hamburg, further advances are anticipated.

‘There seem at the moment
no grounds for fears,
articulated in the early days,
that the laboratory would grow
into a *monstre sacré*, which
would consume too much
of the limited pool of funds
and talent available’

What questions will be answered with the aid of the new diffraction technology is not yet clear. However the report suggests that time-resolved diffraction in the millisecond range may soon become a reality, and with it structural stopped-flow experiments. The system most likely to yield to such an approach is obviously the cross-bridged cycle of muscle, but it is perhaps a valid article of faith that a technique so potent will foment other interesting applications.

Sober document

A few purple passages aside, the report is a sober document that offers few hostages to fortune; it is a pity though that it has come so late and gives no financial details. Many other interesting questions are left unanswered. The report lists a scientific staff of fourteen, a large proportion of them German, and some twenty visiting workers and research fellows. The final pattern of the laboratory has therefore yet to emerge. One wonders, however, where the young postdoctoral workers who are supposed to be the immediate beneficiaries of the institution are to come from. Not presumably from America, for then the EMBL will lay itself open to the charge, often levelled (however unfairly) at the MRC's Laboratory of Molecular Biology in Cambridge: that its unique intellectual

resources have been used to train American rather than indigenous workers.

And if it is to cater for Europeans, who will provide financial patronage? The number of fellowships available in Europe can be counted on rather few fingers, if one excludes EMBO. On the other hand the laboratory would be defeating the aims of its parent body if like a growing cuckoo in the EMBO nest it were to claim an increasing proportion of each year's fellowship allocation, at the expense of the very laboratories around Europe that the fellowship programme was designed to help.

What is reassuring at all events is that the report stands by the principle of the financial independence of EMBL and EMBO. There is therefore presumably no danger that, whatever economic hardships may lie ahead, the laboratory will ever be driven to continue its planned expansion at the expense of the fellowship programme. For nothing as felicitous as the EMBO fellowship scheme has emerged to invigorate European science in many a decade. It was conceived in the clear-sighted conviction that European biological science can become greater than the sum of its parts only through expansion of the scientific community, which in turn demands the kind of fluidity that has long been one of the bases of the American success. The impact of the EMBO fellowships has already been prodigious, and the Founding Fathers of the programme must be aware that it will be remembered in their favour on the Day of Judgement.

The first annual report of the EMBL suggests that as good a start has been made as could have been hoped. There seem at the moment no grounds for fears, occasionally articulated by the churlish in the early days of the project, that the laboratory would grow into a *monstre sacré*, which would consume too much of the limited pool of funds and talent available to the university departments. Indeed, in such a time of blight, it is opportunity rather than talent that is in short supply, and the additional jobs that the laboratory is to provide will be welcome.

As to whether the EMBL will be a success at the level at which it was conceived—as the Oxford historian is supposed to have said when questioned about the effects of the French Revolution, it is too early to tell. All biologists in Europe, and for that matter America, will wish to congratulate Sir John Kendrew on getting this courageous project launched. Many will see its progress as a barometer of the prevailing intellectual climate, and all, no doubt, will wish it well. □

IN BRIEF

Nuclear committee move

Democrats in the House of Representatives last week hammered a large nail into the coffin of the Joint Committee on Atomic Energy by voting to strip the committee of its legislative power. The move, if upheld in the full house when it reconvenes in January, would break the Joint Committee's thirty-year monopoly over nuclear legislation, and it would place nuclear matters in the hands of the committees which are likely to be more critical of the nuclear programme. The vote in the House Democratic Caucus, led by Representative Jonathan Bingham, would divide the committee's legislative authority among the Science and Technology Committee, the Commerce Committee and the Interior Committee, leaving the Joint Committee as a deliberate body with no power to handle

legislation. Similar moves will be discussed in the Senate next month as part of a complete overhaul of the Senate committee system.

Environment Ministers meet

As widely expected, the Council of Environment Ministers of the European Community, meeting in Brussels last week, could not agree on Commission proposals for dealing with the discharge into the aquatic environment of waste from titanium dioxide and paper pulp plants. The difficulty, as on similar issues before, concerned whether controls should apply to emissions directly or indirectly to the environment receiving them. The Council was able to agree to a new five-year (1977-81) environment programme focusing on air, water and noise.

UK-USSR agreement

Anglo-Soviet cooperation on environmental protection is to be extended. The third meeting of the joint UK-USSR Committee on Cooperation in the Field of Environmental Protection, held earlier this month in London, approved a plan for 1977 which includes the establishment of a working group on nature conservation, the setting up of a staged programme on urban transport and the rehabilitation and maintenance of residential areas, a work programme on land reclamation, and a study of possible cooperation regarding gas cleaning and dust elimination. The prevention and elimination of oil spills at sea is to be the subject of feasibility study. Topics are selected not on a basis of absolute priorities, but according to whether they produce a valuable sharing of information.

It is an old familiar story regarding industrial research that when sales decline, basic research is one of the first items to get the axe (rather than the President's plane). The justification is that accumulated knowledge is sufficient to keep things going for at least a while. In 1966, this philosophy became nationwide when President Lyndon Johnson was able to shift the federal support of science away from basic research and towards what is termed "mission-oriented research" or "research in the service of man". He said, for example, "We must make sure that no lifesaving discovery is locked up in the laboratory" (as if this were possible).

Professor Charles Tidball points out that the shift was made possible by anecdotal presentation of information to lawmakers. A factual examination of the background of "applied research" shows, however, that it is actually based largely on fundamental findings.

Decisions as to "what type" of science should be supported, or even permitted, depends increasingly on persuasive language, and today the language must be terse, so as to fit TV programmes. Slogans and phrases such as "environmental impact", "recombinant DNA", "carcinogenic chemicals", "endangered species", "noise pollution", "megavitamin therapy", and "world wildlife" are the current persuaders. They enable complicated matters to be put in neat little boxes that decision-makers can handle.

I was astonished to find recently

that one of the most popular persuaders of today, "food additives", is only eighteen years old. It did not become a category until the Food Additives Amendment of 1958. I regard the term, if you will excuse the cliché, as a pollution of the language, for most users of the phrase seem to think it means a class of substances. Actually

Language in action

THOMAS H. JUKES

it refers to a use to which diverse materials, many of them accepted foods, are put. There is a strong movement "against" food additives, and there is even an organisation "The Feingold Association", dedicated to their exorcism. The members are followers of an allergist, Dr Benjamin

Feingold, who has published a book (many MDs publish books instead of writing scientific articles) about hyperkinesis in children, and its relief, and that of their parents, by a diet containing no "food additives". I have not seen in any writings supportive of the "Feingold treatment" mention of the fact that numerous "natural ingredients" of food are more toxic than additives at levels of permitted usage.

It may be that Dr Feingold has found a way to rid harassed and inactive parents of that nuisance, the "hyperactive child", which, incidentally, is another slogan. But consider a partial list of what must be eliminated from intake or contact: apples, blackberries, cherries, peaches, cucumbers, pickles, tomatoes, ice cream, bakery goods (except "plain bread"), luncheon meats, jam or jelly, gin and all distilled drinks except vodka, tea, beer, wine vinegar, all soft drinks, aspirin, perfumes, toothpaste and toothpowder.

Is it possible that the goodies in this incredibly diverse list share any common biochemical or pharmacodynamic properties that make each and all of them inductive of "hyperactivity"? I find this postulation incredible, but millions of dollars will be spent to seek out the answer. I suggest that this expenditure is yet another example of "language in action".

Perhaps, however, sluggish adults should help themselves to tomatoes, ice cream, gin, toothpaste and perfume to induce hyperactivity.

news and views

Controversy over the extragalactic distance scale

from M. Rowan-Robinson

THE redshift-distance relation for galaxies discovered by Hubble and Lundmark in the 1920s is the most tangible evidence we have for an expanding universe. The constant of proportionality, the Hubble constant, can be interpreted as the expansion time-scale of the universe. Yet in spite of the consumption of many thousands of hours of telescope time, the extragalactic distance scale remains a subject of controversy, highlighted by a disappointingly inconclusive International Astronomical Union symposium at Paris in September.

At the symposium Tammann summarised the massive programme of galaxy distance measurements that he and Sandage have been pursuing, culminating in a value for the Hubble constant, H_0 , of around 50 km s^{-1} per Mpc (for a recent review see *Nature*, **262**, 97; 1976). Yet almost all other workers reporting at the symposium disagreed with the Sandage and Tammann distance scale, preferring a value for H_0 closer to 80. For example, van den Bergh and de Vaucouleurs reported significantly lower distances for members of the Local Group of galaxies, to which our Milky Way galaxy belongs. Hanes' work on globular clusters in galaxies in the Virgo cluster, the nearest of the great clusters of galaxies that determine the Hubble relation on the large scale, led to a distance estimate for Virgo of 12.5 Mpc (1 Mpc = 3.26 million light years) instead of the Sandage and Tammann value of 22. And Tully and Fisher used their 21-cm neutral hydrogen line method to obtain a value for H_0 of 75.

It is therefore fascinating to see in the latest *Astrophysical Journal* (**210**, 7; 1976) Sandage and Tammann's version of this last method. They take Tully and Fisher's data, reanalyse and recalibrate it, and emerge with a Hubble constant of 50.3 ± 4.2 . The 21-cm method depends on a correlation found by Tully and Fisher between the 21-cm hydrogen line

width and the optical luminosity of a spiral galaxy (one has to have some galaxies with distances known more directly to calibrate this relation). The apparent optical brightness of a galaxy then gives the distance through the inverse square law.

Sandage and Tammann use the method to obtain the distance of the Virgo cluster, and compare the result with six other methods (including, ironically, an earlier estimate by Hanes which agreed with theirs). The adopted Virgo distance, 22 Mpc, is then combined in three different ways with the mean velocity of the cluster

to yield $H_0 = 50.3 \pm 7.0$, 50.3 ± 4.2 , 50.3 ± 4.2 . The authors remark "That the values of H_0 from all three methods are the same is clearly fortuitous". If the agreement between these three means at so high a significance level is indeed simply good luck, then heaven protect these authors from bad luck.

Do these disagreements over H_0 , which appear even when the same data is used, matter? Well, first, the actual value of H_0 matters to cosmologists, because by comparing it with the age of our own and other galaxies they can deduce how long

Precise Lamb shift interval

from Peter Knight

FOR two years now, we have had two slightly different theoretical values for the hydrogenic $n=2$ Lamb shift interval. The more recent value, due to P. J. Mohr (*Phys. Rev. Lett.*, **34**, 1050; 1975) is $1057.864 \pm 0.014 \text{ MHz}$, and should be compared with the earlier value of $1057.912 \pm 0.011 \text{ MHz}$ due to G. W. Erickson (*Phys. Rev. Lett.*, **27**, 780, 1971). Published experimental values up to 1975 lacked the ultra-high resolution needed to support one value rather than the other. The 100 MHz natural linewidth of the Lamb transition imposes severe limitations on precision experiments, and great care is needed in the lineshape analysis.

At Harvard, S. R. Lundeen and F. M. Pipkin (*Phys. Rev. Lett.*, **34**, 1368; 1975) used a Ramsey-type separated-oscillatory-field technique combined with a fast atomic beam to achieve resonance widths of one-third the natural width, and an improvement of a factor of 3 in the precision of the experimental value for the $n=2$ hydrogenic Lamb shift, obtaining a value of $1057.893 \pm 0.020 \text{ MHz}$. Unfortunately this still overlaps with and is consistent with both theoretical values. This situation and future prospects were

recently reviewed by Pipkin (*Comments Atom. molec. Phys.*, **5**, 45; 1975).

More recently D. Andrews and G. Newton at the University of Sussex report the results of a new high-precision single-loop experiment, which whilst consistent with the Harvard experiment, manages to discriminate in favour of the new value of Mohr. The Sussex experimental value is 1057.862 ± 0.020 (*Phys. Rev. Lett.*, **37**, 1254; 1976).

It is unlikely that the precision of the Sussex technique can be improved significantly, since (as they say) they are at the limits of available microwave technology. Similarly the lineshape analysis of the separated-field approach is complex. One is, after all, trying to resolve a line centre to better than a few parts per million, when the fundamental natural width is as large as one-tenth of the resonance frequency. Opportunity for further progress seems to rest with the theoreticians. The source of the discrepancy between Mohr's and Erickson's theoretical values is unknown, but presumably is connected with the different ways of computing the self-energy contribution to the Lamb shift.

galaxies took to form. The big bang picture would be in trouble if the expansion time was less than the age of our Galaxy. Second, discrepancies which are such a large multiple of the quoted errors do not enhance the status of observational astronomy. At the moment the onus seems to be on the opponents of the Sandage and Tammann scale to assemble a similar body of observational data. Theoreticians will have to maintain the scepticism about H_0 that the wiser among them have always shown in the past. □

RNA and generation of positional information

from Peter Lawrence

MOST biochemical investigation on developing systems is just conventional biochemistry on a system which happens to be developing, and is not relevant to the understanding of development in terms of the controlling molecules involved. (After all, even developing animals have to make proteins, send acids scooting round the Krebs cycle and so on). Conversely, specifically developmental phenomena, such as regulation are difficult to approach from a biochemical point of view. But several insects, including the tiny dipteran midge *Smittia*, undergo what Sander (*Wilhelm Roux Archiv.*, 167, 336; 1971) has called "negative regulation". An embryo regulates by reacting to experimental damage, such as removal of tissue, by respecification of cells so that normal development is restored. In negative regulation, however, respecification proceeds abnormally so that a monster develops. These striking changes in *Smittia* have provided investigators with a handle on the molecular mechanisms which may be involved in specifying that pattern.

Normally the insect consists of a number of segments arranged in order from head to tail; each segment is uniquely patterned. The segment order in most insect eggs becomes defined at blastoderm (when the embryo is just a hollow ball of cells) and depends only on the positions of the cells forming at the surface of the egg, not on the lineage of their nuclei. There is thus positional information in the egg. Experiments on other insects (see Sander, *Ciba Foundation Symp.*, 29, 241; 1975) suggest that the positional information is in the form of a gradient which is made by an interaction between two determinants, an anterior and a posterior one, at the poles of the egg. Kalthoff working in Sander's

laboratory (Kalthoff, *Roux. Arch.*, 168, 63; 1971) discovered that local ultraviolet irradiation of the anterior pole of cleaving *Smittia* eggs (the nuclei were untouched by irradiation) caused up to 100% of the embryos to change their segment pattern from 123456789 to 98766789 (Fig. 1). This aberrant pattern is called a 'double abdomen'. The targets to ultraviolet were localised in the egg cytoplasm and distributed unevenly in the anterior third of the egg, becoming most concentrated at the anterior tip. The damage done by ultraviolet was not violent: nuclei subsequently entered the irradiated region and developed normally into cells. Only the positional information, and hence the segment pattern, seemed to be altered. Kalthoff found the ultraviolet damage could be repaired by visible light so that normal embryonic development was restored; this suggested that nucleic acid might be the target. Action spectra (Kalthoff, *Photochem. Photobiol.*, 18, 355; 1973) showed peaks in both the protein and the nucleic acid regions.

This line has now been taken one step further by Kandler-Singer and Kalthoff (*Proc. natn. Acad. Sci.*, 73, 3739; 1976). They were able to produce double abdomens by gently puncturing the anterior pole of the egg in water containing RNase ($0.8 \mu\text{g ml}^{-1}$). Although about half the embryos failed to develop at all, 47% of those which did made double abdomens. In water only some 5% failed to develop and none grew up with double abdomens. With an elegant control they demonstrated that it was actually the RNase activity which was responsible for altering the segment pattern. They treated the eggs with two fragments of RNase each of which is inactive separately (RNase S (active) is split by TCA fractionation into S-peptide (inactive) and S-protein (hardly active)). When solutions of the two fragments are mixed RNase activity returns. The percentage of double abdomens was nil with S-peptide, 1 with the S protein

Diagrammatic representation of the induction of a double abdomen in *Smittia* eggs by ultraviolet irradiation of the anterior pole region, puncture at the anterior pole or centrifugation with the long egg axis parallel to the centrifugal force. (From *Insect Development*, edited by Lawrence, P., Blackwells Scientific, Oxford and London, 1976.)

and about 40 both with complete RNase S and with the two fragments dissolved together. Puncturing of the eggs elsewhere than at the anterior pole produced no double abdomens. Double abdomens were formed only when the experiment was performed up to the blastoderm stage of embryogenesis. These results together with those mentioned earlier, strongly suggest that an RNA moiety is an essential component in the generation of positional information in the egg. Kandler-Singer and Kalthoff suggest it might be mRNA that is translated during cleavage.

The next stage in this investigation will ideally be the development of a positive assay in which the damage done by ultraviolet will be repaired by the injection of extracts into the anterior pole of the egg. This could lead to the first isolation of a molecule specifically involved in the generation of positional information and perhaps to some inkling as to what gradients are in molecular terms. □

Structural gene for sex pilin

from J. P. Beard

A RECENT paper from Charles Brinton's laboratory in Pittsburgh reports on an important aspect of the mechanism whereby 'male' Gram-negative bacteria are able to transfer genetic material to 'female' bacteria by conjugation. This subject has been of great interest to microbiologists for many years, since not only does the conjugation process provide a useful research tool for probing the genetic composition of *Escherichia coli* and related species, but it is also usually mediated by genes carried on plasmids in the male or donor cell. Plasmids are small extrachromosomal pieces of DNA, carried by a wide variety of bacterial genera, which are capable of autonomous replication in the host cell, and which can often transfer both themselves and chromosomal DNA in the conjugation process. Plasmids are also important as vectors of multiple antibiotic resistance genes, or of genes which confer other important properties on the host such as colicinogeny or enterotoxin production (see, for example, the *Ciba Foundation Symposium on Bacterial Episomes and Plasmids*, J. and A. Churchill, 1969), and have recently taken on a new lease of life as vectors for "genetic engineering", currently the subject of intense public discussion.

Studies of one such plasmid, the sex factor F (Hayes, *The Genetics of Bacteria and their Viruses*, Blackwell,

1968), have shown that male, or F^+ , cells produce filamentous appendages on their surfaces—sex pili, which are required for both conjugation and sensitivity to male-specific bacteriophages. In addition, it has been demonstrated that sex pili are composed of a single protein, sex pilin, of molecular weight 11,400, which contains one mol of glucose and two mol of phosphate per mol of pilin, while genetic studies have shown that the transfer process is controlled by at least twelve genes on the plasmid whose order has been established by deletion mapping to be

traJ traA traL traE traK traB
traC traF traH traG traD traI

It has been shown that the product of the first of these genes, *traJ*, is required for the expression of the other genes, *traA* to *traI*, which constitute a single operon (Willets, In *Microbial Drug Resistance*, edit. by Mitsuhashi and Hashimoto, University Park Press, Baltimore, 1975; and Helmuth and Achtman, *Nature*, **257**, 652; 1975). Mutants in any of the first nine genes (*J. A. L. E. K. B. C. F* and *H*), and some in the tenth (*traG*), lack sex pili, and complementation analysis of a range of the mutants in the presence of another F -like plasmid (R100-1), which specifies slightly different sex pili, suggested that *traA* was a likely candidate for the F pilin structural gene (Willets, *Nature new Biol.*, **230**, 183; 1971). This has now been confirmed in a series of elegant experiments by Brinton's group (Minkley, Polen, Brinton and Ippen-Ihler, *J. molec. Biol.*, **108**, 111; 1976) in which they took advantage of the fact that sex pilin contains only two tyrosine residues per molecule. By using amber (nonsense) mutants in the *traA* gene which were originally isolated by Achtman *et al.* (*J. Bact.*, **106**, 529; 1971) and a *supF* host strain which suppresses amber mutations by inserting a tyrosine residue at the amber site during protein synthesis, Minkley *et al.* have been able to isolate the sex pili specified by the mutant plasmid in the suppressing host. Subsequent iodination of the pilin protein derived from these sex pili, using radioactive iodine-125, and preparation of peptide maps (2-dimensional separation on thin layers of cellulose) after tryptic digestion, has revealed three radioactive spots in the case of tyrosine-suppressed *traA* sex pilin compared with two radioactive spots from pilin obtained from serine-suppressed *traA* sex pili (produced by a *supD* host carrying the *traA* mutant plasmid).

This neat identification of *traA* as the structural gene for sex pilin is a first step towards a detailed biochemical analysis of the biosynthesis of sex pili, and it should form the basis of a clearer understanding of the roles of the re-

maining *tra* genes in the processes of conjugation and male-specific phage infection. In the long term, this work could provide molecular biologists with a unique model for study of a complex surface polymer, specified by an easily-manipulated plasmid genome, whose biosynthesis and assembly is likely to involve important interactions with other, host-specified surface components of the bacterial cell. □

Watchers of the skies

from David W. Hughes

NETWORKS of all-sky cameras are coming and going in modern astronomical research. Coming because the Russians are just installing an enormous new system in the south of the USSR. Going because, almost simultaneously, the American Smithsonian Institution is abandoning and dismantling its Prairie network.

Zotkin, Simonenko, Fedynsky and Khotinok (Meteorite Committee of the USSR Academy of Science) and Kramer (Astronomical Observatory of the Odessa University) discuss the Russian Network in a recent paper in *Meteoritika* (USSR Acad. Press, **35**, 3; 1976). This will have 39 camera stations separated by 180 to 240 km spaced throughout 900,000 square km of the River Don basin, the Ukrainian and Moldavian Republics and the North Caucasus. This is a relatively flat, densely populated part of the country with well-developed communication links. It is hoped that the network will provide about 100 photographs of fireballs brighter than -9.0 visual magnitude over a 5-year period. The velocity, time of appearance, atmospheric trajectory and previous orbit of each of the fireball-producing meteoroids can be obtained by careful analysis of the photographic plates. It is estimated that between 1 and 3 of the fireballs photographed will also be so bright that the causative interplanetary body will not completely ablate in the atmosphere and a part of it will fall to ground as a meteorite. The fireball's atmospheric trajectory enables the area of fall to be calculated and it is hoped that a detailed search of this region will lead to the recovery of the meteorite. This will not only increase the number of meteorites available for analysis but much more importantly will provide a special class of meteorites which have well-known orbits. Only three meteorites, Příbram, Lost City and Farmington are in this special category so far.

The Russian system will be the fourth in Europe. The first one to be set up was over the whole of Czechoslovakia (*Bull Astr. Inst. Czech.*, **16**, 15; 1965)

which has lately been joined by a similar network covering the south of the Federal Republic of Germany. There is also a large network in the British Isles run by the Meteor Section of the British Astronomical Association (*J. Br. Astr. Assoc.*, **85**, 150; 1975). In North America a Canadian system watches over southern Alberta, Saskatchewan and Manitoba. The old Prairie network (*SAO Special Report* No. 193, 1965) used to cover all of South Dakota, Nebraska, Kansas, Oklahoma, Mississippi, Iowa and Illinois. It was hoped that this Prairie network would lead to the recovery of at least one meteorite per year but unfortunately this was not to be. Many fireballs were photographed and our knowledge of these awe-inspiring objects increased enormously as a result of the data collected but paradoxically it was found that few brilliant fireballs actually lead to meteorite falls. The Lost City meteorite was the only one found during all the years of operation.

A second use of these networks has recently come to light. At the Ondřejov Observatory near Prague, Czechoslovakia, an Opton-Distagon fish eye objective on a large (9×12 cm) plate camera is used to photograph systematically the entire celestial hemisphere each moonless clear night. This has been done since March 1975 when a programme was started to replace the old 36 cm convex mirror-type all sky cameras previously used throughout the Czechoslovak network by these newer cameras. The image quality produced by this fish-eye lens is excellent. The camera is driven and with the usual 4 h exposure, reaches a magnitude limit of +11 and has a resolution of 1 min arc. The changes in image quality as far as 70° from the centre of the field of view is still small enough to be removable by small correction terms. Boček, Cepelch, Ježková and Novák used the camera to take a set of 13 photographs of Nova Cygni 1975. The image definition was so good that there was an almost linear dependence of star image diameter on stellar magnitude. Over 20 comparison stars could be used on each plate, all at a zenith distance of less than 40° and with comparative ease the visual magnitude (*V*) of Nova Cygni could be obtained to a precision of ± 0.10 magnitudes. These observations, made between August 31.8 and September 2.9, are reported in the latest edition of the *Bulletin of the Astronomical Institutes of Czechoslovakia* (**27**, 190; 1976).

With the ever increasing use of these sophisticated cameras throughout Czechoslovakia it is hoped that, as well as leading to meteorite finds, the

rise in brightness of new novae can be accurately plotted as well as the decay. With a limiting magnitude of +11 it is hoped that many more than the 2.2 novae normally discovered each year will be found. □

Probing specific translational controls

from Martin Blundell

In principle, the expression of genetic information may be regulated either at transcription or at translation. Control of transcription eliminates the synthesis of unnecessary messenger RNA but control of translation could act more quickly, particularly in eukaryotic cells, where messenger half-lives are measured in hours.

Most control seems to be exerted at transcription or possibly (in eukaryotes) during the processing and transport of mRNA from the nucleus. Nevertheless, translational control is clearly established in eukaryotic cells. In reticulocytes, for example, the translation of globin and other mRNAs is controlled by diverse agents such as hemin and double-stranded RNA. Other cells respond in the same way to virus infection and alteration of their growth medium. In general, this sort of translational control appears rather unspecific. Thus, haem deficiency shuts off all reticulocyte protein synthesis, not just the synthesis of globins.

Translational controls seem more difficult to detect in *E. coli*, where message half-lives are much shorter (even when expressed as a fraction of the doubling time of the cell). Translational controls do exist, however, and they may be more specific than those in eukaryotes.

When *E. coli* is infected by phage T7, a T7 gene makes a translational repressor which switches off host protein synthesis (Herrlich *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 1088; 1974) presumably to maximise production of T7 proteins. Another kind of translational control is seen during infection by phage λ (Ray and Pearson, *J. molec. Biol.*, **85**, 163; 1975; *Nature*, **263**, 647; 1976). The late genes of λ are all transcribed at about the same rate, but the number of protein molecules made from different genes varies nearly a thousand-fold. Since the functional lifetimes of the various messages are all about 2½ min, the differences in quantity of protein observed can only be explained by varied efficiencies in translation or possibly by differences in the stability of the proteins themselves.

In uninfected *E. coli* there seems to be a control of translation of some inducible messages. In three rather different cases, the translation of β -galactosidase message is impaired when general protein synthesis appears normal. Ennis and Kievett (*J. biol. Chem.*, **251**, 2854; 1976) have studied cells recovering from inhibition of protein synthesis by either chloramphenicol or deficiency of potassium ions (the latter avoids difficulties which might arise from residual antibiotic). In these cells, *lac* mRNA is made but is only poorly translated. Other proteins as large as β -galactosidase and larger are being made, so the effect is not just a lesion in protein synthesis. The message can function *in vitro* to make the amino-terminal part of β -galactosidase, but not even this part is made *in vivo*. Although more complex explanations remain possible, the simplest is that some control on translation is operating in the recovering cells. The same authors also report under-translation of *lac* mRNA in *lac* O^c mutants and *trp-lac* fusion strains (*J. Bact.*, **125**, 1220; 1976).

The most recent work of Herrlich and Schweiger (*Proc. natn. Acad. Sci. U.S.A.*, **73**, 3386; 1976) suggests translational control of a number of inducible genes. The main thrust of their paper is to determine the mode of action of nitrofurans, a class of synthetic antibiotics in widespread use as food additives and in medicine. When low concentrations of nitrofurans are added to cultures, the synthesis of inducible proteins (β -galactosidase, tryptophanase, galactokinase and others) is inhibited while other proteins are unaffected. The possibility that this effect is mediated by cyclic AMP and catabolite activator protein is eliminated.

Three lines of evidence indicate that the drug acts on translation. First, in EDTA-permeabilised cells, nitrofurans act on β -galactosidase synthesis more rapidly than do rifampicin or actinomycin. Second, in strains where *lac* transcription is fused to nitrofuran-resistant genes (either the *trp* operon or *lac i^a*) β -galactosidase synthesis remains nitrofuran sensitive. However, when a deletion fuses the peptides made by the *lac i* and *lac z* (β -galactosidase) genes, the production of the fusion peptide is nitrofuran resistant. Third, *in vitro* synthesis of galactokinase is equally sensitive to nitrofuran whether directed by DNA or RNA, whereas *gal* transcription is unaffected.

If nitrofurans are to act specifically on the translation of certain proteins, there must be some recognition signal. The only stage at which recognition could easily occur is at the initiation of translation. This conclusion is supported by the nitrofuran-resistant

synthesis of the *lac* repressor: β -galactosidase fusion peptide and by a further experiment on galactokinase synthesis *in vitro*. When preformed polysomes are used for galactokinase synthesis, so that ribosomes have already initiated, nitrofuran no longer inhibits. Apparently a group of messengers carries a signal different from other messengers, and the translational machinery is able to recognise this signal. Such signals could presumably have evolved to provide specificity in a translational control system.

How much use does *E. coli* make of translational control? Unless a message is completely inactivated, translational control would generate polysomes with fewer ribosomes than usual, but electron micrographs (for example, *Cold Spring Harbor Symp. quant. Biol.*, Miller, **35**, 505; 1970) show that the density of ribosomes on mRNA is remarkably uniform. □

Plumes in an expanding Earth

from Peter J. Smith

THE expanding Earth hypothesis has been part of the geophysical backdrop for at least 20 years. Indeed, its origin in physics may be traced back even further, to Dirac (*Nature*, **139**, 323; 1937) who first proposed that the gravitational constant may not be a true constant but may be slowly decreasing with time. More recently, Steiner (*J. Geol. Soc. Aust.*, **14**, 99; 1967) has suggested that the gravitational constant may be varying cyclically rather than decreasing monotonically, but neither this idea nor Dirac's has received convincing proof. The point is, however, that during a period in which the gravitational constant is decreasing, the forces between particles would also be decreasing, and the volume of the Earth would therefore be increasing.

On the whole, Earth expansion has found little favour among geologists and geophysicists. It has a few very strong supporters, notably Carey (*Earth Sci. Rev.*, **11**, 105; 1975); and various workers have from time to time tried to test the hypothesis by, for example, palaeomagnetism (which can be used in theory to detect changes in the Earth's radius) and the fitting of continents onto globes with reduced radii. But such attempts have never been entirely successful, often because the data available were insufficiently accurate to resolve expansion of the Earth at low rates. The real reason for the expansion hypothesis's lack of success, however, is less the evidence against it than the

fact that it seems to be unnecessary. In other words, few are convinced that there are any major phenomena that cannot be explained by plate tectonics.

But this is far from saying that the expansion has not occurred. The question remains unresolved; and it is still open to anyone to test the hypothesis against any appropriate data. This is precisely what Stewart (*Geophys. J.*, **46**, 505; 1976) has now done using hot spots and mantle plumes. Of course, mantle plumes are as controversial as the expanding Earth. There are certainly hot spots at the Earth's surface, but whether they reflect underlying crustal-upper mantle phenomena or whether they are due to thin columns rising from the core-mantle interface is still a matter of debate.

One of the main attractions of mantle plumes, however, is the possibility that they might be laterally stable and thus provide a frame of reference fixed to the mantle. Evidence on this point is mixed, with some workers claiming to have shown that plumes remain fixed with respect to each other and others claiming to have detected relative motion. But as Stewart points out, all such exercises have been carried out assuming the Earth to have maintained a constant radius. So how do the data appear against the background of an expanding Earth?

To find out, Stewart has determined the great circle angular distances between the members of pairs of hot spots for three times—the present, 50 Myr ago and 120 Myr ago—assuming a constant terrestrial radius. For points within the same plate, the average ratio of the 50 Myr angles to the present angles is 0.98 ± 0.04 which is not significantly different from unity. The average ratio of the 120 Myr angles to the present angles, however, is 0.88 ± 0.03 . The errors on these figures are estimated to be up to 5%, largely because of the difficulty of locating accurately the centres of hot spots which may be 150 km or more across. But taken at face value the older figure suggests that the average great circle separation between members of hot spot pairs could have increased by 11–17% over the past 120 Myr and even up to 6% over the past 50 Myr.

One explanation of these remarkable results is that the hot spots are moving with respect to each other at relative speeds of $0.5\text{--}2.0\text{ cm y}^{-1}$ across the surface of an Earth with constant radius. But in that case it would be strange that the members of most pairs are moving away from each other, for in a random system one would perhaps expect as many hot spots to be converging as diverging. On the basis of Stewart's evidence, therefore, it seems much more likely that the geocentric angles between the supposed mantle

plumes remain roughly constant whilst the Earth expands to produce divergence of the hot spot locations at the surface.

As Stewart admits, his results can hardly be said to prove that the Earth has expanded. But they are a small step in that direction. □

Balancing the nutrient budget

from Peter D. Moore

THERE have been many commendable attempts to reduce to quantitative terms the influence of catastrophes on the flow of energy through and the cycle of nutrients within ecosystems. Some of the most carefully monitored experiments have come from the Hubbard Brook ecosystem studies in New Hampshire (for example, Likens *et al.*, *Ecol. Monogr.*, **40**, 23; 1970) and the Coweeta catchment area studies in North Carolina (for example, Swank and Douglas, *Science*, **185**, 857; 1974). In both these experimental areas, deciduous forest cover has been destroyed and the resultant changes in runoff water and nutrient losses have been observed. At neither of these sites, however, have the consequences of these hydrological and chemical changes been considered from the point of view of those ecosystems which receive the effluent generated by the catastrophe.

A study has recently been undertaken in Minnesota by Wright (*Ecology*, **57**, 649; 1976) in which the chemical impact of forest fire upon the nutrient budget of receptor lakes has been determined. The forested catchments of Meander Lake and Lamb Lake in the north-east of Minnesota were extensively burned in a serious fire in 1971. Changes in the nutrient budget and hydrology of these lakes were compared with those of Dogfish Lake, a similar site whose catchment lay outside the burned area.

The percentage increase in runoff attributable to the fire was 30% at Lamb Lake and 60% at Meander Lake. The latter value is considerably larger than values obtained after clear felling catchment areas at Coweeta and Hubbard Brook (15% and 40% increases respectively) and the reason for this may be the loss of the absorptive moss and humus layers after the fire in Minnesota. As it moves through the system, water may receive and may also lose various ions. On arrival at the ground, precipitation may move for a short distance over the surface, particularly if the soil is frozen. In burnt areas this water becomes enriched with phosphates. On percolating into the soil

The ecology of dragons: a reply

I AM glad that Robert May thought my article (Hogarth, *Bull. Brit. ecol. Soc.*, **7**, 2; 1976; May, *Nature*, **264**, 16; 1976) seminal; I must, nevertheless, disagree with him on one of his criticisms. In classifying the wyvern and cockatrice separately from the dragon, he attaches more significance to limb number than to other characteristics which these three types held in common. In particular, I refer to their supernatural qualities which seem to me to be of sufficient importance to justify setting them apart in a taxonomic category separate from that of the vertebrates. Four legs do not make a tetrapod; it is no more logical to include wyverns and cockatrices with conventional vertebrates than to classify a 12-legged dragon as a myriapod. Convergent evolution has indeed occurred to a remarkable extent, but between dragons and their allies on the one hand and vertebrates on the other. Not, as May suggests, between vertebrates (including the wyvern and cockatrice) and dragons.

My estimate of 5,000 years BP for the emergence of dragons is therefore feasible. The total dependence on human imagination for their existence (a unique ecological relationship) precludes an origin earlier than, say, the late Pleistocene. The absence of convincing representations of dragons in upper Palaeolithic art, and their frequent occurrence in literature and art from the time of Babylon onwards, indicates the chronological limits on the possible time of emergence. Between these limits, 5,000 years ago seems a reasonable, albeit imprecise, estimate.

P. J. HOGARTH

these phosphates are adsorbed onto soil particles, but the general cationic load of the water is increased. Stream water is considered to be equivalent chemically to this subsurface flow of water in the soil.

Wright determined nutrient budgets of phosphorus and various cations by monitoring input from precipitation and output in streamflow. The difference between these two rates is equivalent to the weathering input less any change in storage capacity in the system (including biomass growth). It is regrettable, though understandable, that these two components in the budget cannot be separated, but considerable additional measurements

would be necessary in order to achieve this. In the absence of such information, however, conclusions should be tempered with caution. For example, Wright states that nutrient cycling in the undisturbed forest is efficient, with only minor amounts leaking from the system. At the control site, Dogfish Lake, $13.7 \text{ mg m}^{-2} \text{ yr}^{-1}$ P arrives in precipitation and only 1.5 leaves in runoff. Rather than invoke the terms 'efficiency' or 'conservation' in such a situation, one should suspect an increasing storage capacity, probably due to biomass growth. If there were no storage change then inputs should be equalled by outputs, so the terms 'efficiency' and 'conservation' are not particularly informative in nutrient budget studies.

It is evident from Wright's data, however, that the output of nutrients at the burned sites exceeded expected values based on extrapolation from the control data. Such figures for increased discharge as 26% for Ca, 29% for Mg, 265% for K, 65% for Na and 93% for P were obtained from the Meander Lake catchment. Thus water entering the lakes had been substantially enriched in both phosphorus and cations.

Input of nutrients to the lakes is derived from runoff water and also directly from precipitation. At his control site Wright found that runoff was the major source of cations, but that precipitation accounted for over 80%

of the phosphorus input. This is presumably due to the adsorptive properties of the soils for phosphorus. At Meander Lake, after catchment burning, runoff inputs were increased yet further for the cations, and for phosphorus were brought up to the same level as that derived from precipitation. The total increase in phosphorus load at Meander Lake as a result of this change was 38%. In Wright's opinion this lies within the kind of year to year variation expected in phosphorus supply and does not represent a major eutrophication episode. If this is so, then the adsorption of phosphorus in the soil of the catchment is critical for the maintenance of stability of lakes in periods of catchment disturbance. □

Man's influence not yet felt by climate

from John Gribbin

THE message conveyed by Professor B. J. Mason, Director-General of the UK Meteorological Office, in a recent lecture was—don't panic. The theme of Mason's lecture (given to the Royal Society of Arts on December 1) was "Man's Influence on Weather and Climate", and his conclusion was that the climatic system is so robust, and contains so much inherent stability through the presence of negative feedback mechanisms, that man has still a long way to go before his influence becomes great enough to cause serious disruption to the natural climatic system.

Mason began his discussion by setting the influence of man in the context of the natural climatic changes that occur continually, pointing in particular to fluctuations of temperature in the United Kingdom during the three centuries for which instrumental records are available. In the past, fluctuations on the scale of 1°C variation in the annual mean temperature have had less impact on society than similar changes may have in the future; as Mason stressed, the present large world population and inadequate food reserves now put the agricultural system under unprecedented strain. "There is no question that climate is variable and that variations have a greater social and economic impact than ever before", so that changes of 1°C in the long term mean cannot be ignored—such a variation in the United Kingdom could, for example, change the length of the growing season by three weeks. But is man's influence yet approaching even this level?

Three anthropogenic influences have been widely cited as potential causes of climatic disaster: the "greenhouse

effect" caused by CO_2 from burning fossil fuels; cooling produced by dust in the atmosphere; and the effects of chlorofluorocarbons and supersonic aircraft on the stratospheric ozone layer. Mason's analysis of the problems hinged upon the computer modelling of the atmosphere which is the forte of the Met Office, and the numbers he produced were surprising, if reassuring, to at least some members of his audience. A dust layer in the stratosphere thick enough to cut off 4% of incident solar radiation, for example, warms the upper atmosphere by as much as $10\text{--}20^\circ\text{C}$, but produces no detectable effect on the troposphere in the models. And this conclusion may be borne out by events in the real atmosphere after the volcanic eruption in Bali in 1962, when the temperature of the stratosphere increased by some 6°C without any observable effects, according to Mason, on the lower atmosphere.

The ozone problem has been highlighted by controversy surrounding Concorde and spray cans, widely reported in *Nature*. Both the Met Office and American models have now shown that even a fleet of 500 SSTs flying for 5 hours per day each would not reduce the ozone content of the stratosphere by more than 1%, and although the hazard from spray can propellants seems greater, even there release of "freons" could continue at the present 700 kt yr^{-1} until 2100 AD before ozone would be reduced by 8%. Mason feels that the decision in the US to ban such propellants is over hasty, not least because if release at the present rate continued for another 5 years the climate modellers would have enough hard figures to produce better models of what is going on.

But the can is now being banned, at least in the US, and we are left with the release of CO_2 as man's only real, quantifiable contribution to climatic change yet or in the near future. Having cautioned that if the effect is real, something must have offset it in recent decades, since the Earth has actually been cooling down, not warming up, Mason suggested that within 50–100 years the effects of CO_2 release into the atmosphere will produce a warming of $1\text{--}2^\circ\text{C}$, well into the range significant for our present global society. Computer modelling indicates that rainfall patterns would be shifted by 5–10%, but the models are not yet sophisticated enough to detail the effects on specific regions of the globe. There is, says Mason, a real and significant effect here which must be investigated further with bigger and better models—but there is time to develop the necessary models and no need for panic induced by the prophets of doom. □

A hundred years ago

A NEW STAR IN CYGNUS. — On November 24, at 5h 41m P.M., the director of the Observatory at Athens, Prof. Schmidt, remarked a star of the third magnitude not far from ρ Cygni, which was not visible on November 20, the last clear evening previous. Its position from observations with the refractor was found to be in R.A. 21h. 36m 50.5s., N.P.D. $47^\circ 40' 34''$ for the beginning of the present year. At midnight its light was more intense than that of η Pegasi, which is rated a third magnitude by Argelander, and very yellow.

Direct intimation of this discovery was given by Prof. Schmidt to M. Leverrier, and the Paris *Bulletin International* of December 6 contains the few particulars concerning this star which the generally unfavourable weather up to that date had permitted to be put upon record. M. Paul Henry estimated it of the fifth magnitude, so that as in the cases of the similar suddenly-visible stars of 1848 and 1866, it would appear to have remained but a very short time at a maximum. He considered the colour "greenish, almost blue" by comparison with Lalande 42,304, not far distant.

From *Nature*, 15, December 14, 146; 1876

review article

Significant journals of science

Eugene Garfield*

In 1974 the Science Citation Index (SCI) covered about 401,000 articles and communications in 2,443 scientific and technical journals. They cited about 3.2 million different publications an average of 1.8 times each. In this article some results of an analysis of more than 5 million citations in the references of journal articles indexed for the SCI in 1974 are presented and an attempt is made to interpret of those results in the light of an earlier study of 1969 citations.

THE basic information recorded in the *SCI* for citing and cited papers is a "condensed citation." It gives first author, year, journal, volume, and page. The citing-cited pairs can be sorted and subsorted in various ways, as one's interests dictate. Sorting by cited author produces the *Citation Index* section of the *SCI*. Sorting by citing and cited journals produces the two major sections of the *Journal Citation Reports (JCR)*.

ISI's *Journal Citation Reports* is an index of journal-journal links based on a grouping and summation of condensed citations using journal rather than author as the primary sorting key. A preliminary *JCR*, based on an analysis of 1969 references¹, appeared in 1972². This year the *JCR* became a regular section and volume of the *SCI*³. It is the source of the 1974 citation data discussed here.

In this report I have used two indicators of journal significance: total citations and impact. The first is simply the number of times a journal was cited in 1974. Impact, on the other hand, is a measure of the relationship between citations and articles published. For this report, impact was calculated by dividing the number of 1974 citations of 1972 and 1973 articles by the number of articles published in 1972 and 1973. For example, the 817 articles published in 1972 and 1973 in the *Journal of Molecular Biology* were cited 6,129 times in 1974. The impact of the journal is therefore 7.502.

Fig. 1(a) lists the 206 journals most cited in 1974. Fig. 1(b) lists an additional 78 journals whose 1972 and 1973 articles only—rather than articles of any and all years, as in Fig. 1(a)—were highly cited in 1974. (The total of 284 journals in Fig. 1(a) and (b) corresponds to the number of journals listed in Fig. 2(a) and (b), which have impacts greater than 2.) In most cases (63%) these journals began publication in the 1960s and 70s. Older journals like the *Comptes Rendus* rank well in Fig. 1(a), mainly because there is so much that can be cited. Fig. 1(b) is a needed supplement to the list in Fig. 1(a), since the journals have high current citation but lack historical mass to push them up into the top of a list ranked by total citations.

Figures 2(a) and (b) show the 284 journals with impacts greater than 2. Fig. 2(a) lists 206 primary journals. Fig. 2(b) lists 78 review journals; the impact of review journals is generally higher than that of primary journals.

Figure 3 lists journals that rank highest in citation and

impact for three specialties: mathematics, botany, and astronomy/astrophysics. The differences in average impact and citation between the three illustrative categories indicate why comparisons between journals in different specialties may be invidious. For example, it would be foolish to conclude merely on the basis of citation counts that *Astrophysical Journal* is a "better" journal than *Annals of Mathematics*, or to hypothesize without a great deal of study which serves its own field "better."

Variation from field to field is determined by the interplay of several factors. Perhaps the most important is the average number of references per paper in the field⁴. In general, mathematicians cite less than half as many papers as do biochemists. Engineers on the other hand cite books as heavily as journals, as do social scientists. Furthermore, calculation of impact based on 1972 and 1973 publications is bound to affect the impact of journals in a field like mathematics, where citation of older literature is far more common than in others. Thus, the impact of mathematics journals would be higher if calculated on the basis of 1970 and 1971 publications.

It seems necessary to point out the obvious, as I have done in preparing Fig. 3, because one short-sighted criticism of the *JCR* has been that its listings and rankings are indiscriminating. One can get from the *JCR* information on journals within disciplines for intradisciplinary comparison. None of the mathematics journals listed in Fig. 3 was cited enough to appear in Fig. 1(a), but the citation counts and impact factors show plainly that the two leading mathematics journals are *Transactions of the American Mathematical Society* (on the basis of total citations) and *Acta Mathematica* (on the basis of impact). In both citation and impact the average mathematics journal ranks lower than the average astronomy or botany journal.

If one wishes to add to a general-science collection the two or three leading journals of mathematics, botany, or astronomy/astrophysics, one must examine longer lists and select from them the top journals in each specialty, as I have done in preparing Fig. 3.

The remarkable stability of the significant journals of science is attested by their continued high citation and impact. Of the 206 journals most cited in 1969, 169 remain among the top 206 in 1974. One may regard the changes as the result of healthy competition. The 37 journals that dropped from the 206 most cited between 1969 and 1974 rank between 224 and 426 in the complete listing that appears in the *JCR*⁵.

*Institute for Scientific Information, Philadelphia, Pennsylvania 19106.

Fig. 1a. Journals most highly cited in 1974. Journals are listed in descending numerical order of total citations in the references of 1974 issues of journals processed for the *Science Citation Index*. A: rank in terms of total 1974 citations. B: rank in terms of total 1969 citations. C: total 1974 citations. D: 1974 impact. E: total 1974 citations of 1972 and 1973 articles. F: rank in terms of 1974 citations of 1972 and 1973 articles. An asterisk before a journal title indicates that counts for sections, retitled continuations, translated versions, and so on, have been combined with those for the original; the number in parentheses after the journal title indicates the number of such sections, and so on, that went into the combination, including the original. b. Journals whose 1972 and 1973 articles were highly cited in 1974. Journals are listed in descending numerical order of total 1974 citations of their 1972 and 1973 articles. Journals ranking higher in this respect will be found among the journals listed in Fig. 1a. See the legend of Fig. 1a for significance of the column markers. An asterisk before a journal title indicates that counts for sections, retitled continuations, translated versions, etc., have been combined with those for the original; the number in parentheses after the journal title indicates the number of such sections, etc., that went into the combination, including the original. The date of a journal's inauguration follows its title.

Perhaps the point to be stressed in presenting these data is the bibliographic law of concentration⁶. When the *SCI* was first reviewed in *Nature* more than a decade ago⁷, the scope of its journal coverage was called into question. I believe time has shown beyond doubt that the important literature of science is encompassed by fewer than 1,000 journals. And even fewer account for the truly significant. Of some 45,000 serials of all kinds received by the British Lending Library, two-thirds are rarely, if ever, subject of request. A small core of about 5,000 accounts for almost 80% of all requests⁸.

Fig. 2a, High-impact journals in 1974 (excluding review journals). Journals are listed in descending numerical order of 1974 impact factor. b, High-impact review journals. A: rank in terms of 1974 impact; B: 1974 impact; C: 1969 impact; D: total 1974 citations of 1972 and 1973 articles; E: total number of 1972 and 1973 articles.

In using the data presented here, one should be aware that we revised our definition of "source items" used to calculate impacts. In 1969 we included as source items much material (editorials, non-scientific and non-technical correspondence, news notes, and so on) that does not by its very nature invite citation in scientific and technical reports. This policy worked to the disadvantage of some major journals. Our redefinition accounts in part for the changed impact in 1974 of journals like *Nature*, *Science*, *Lancet*, *Journal of the American Medical Association*, and *British Medical Journal*.

What is the significance of journal impact? By demonstrating that only 150 journals have impacts greater than 3, I believe we have established the futility of discussions based on the assumption that the average library must acquire and store thousands of journals. Since the average impact in 1974 was 1.015, any of the journals listed in the figures is likely to be a good candidate for selection.

Fig 2(b) shows clearly the importance of review journals, confirming our earlier studies. Their extraordinary impact, along with a surge in the number of review-type articles and publications, led to ISI's decision to publish *Index to Scientific Reviews*.

Clearly, a large part of the scientific record is of low impact. Only careful study can show whether this fact

Fig. 3 Significant journals in three scientific specialities. Each list gives journal, (A) total 1974 citations, (B) impact factor, (C) total 1974 citations of 1972 and 1973 articles, (D) number of 1972 and 1973 articles. Journals are listed in alphabetical order. The botany journals include all with more than 600 citations or an impact greater than 1. The astronomy/astrophysics journals include all with more than 400 citations or an impact greater than 0.8. The mathematics journals include all with more than 500 citations or an impact greater than 0.5.

supports or contradicts the idea that science is built on the accumulated results of average effort that prepare the way for breakthroughs¹⁰. In any event, the data seem to me to warrant an examination of the cost-effectiveness of the present publishing system. Journals devote to the mass of rarely cited papers the same resources as to the small part that citation analysis shows to be important. Less than 1% of all papers cited will be cited ten or more times in any annual *SCI*. Although more than 40 million references have been processed for the *SCI* during the past fifteen years, only 116,400 papers have been cited ten times or more in any one year.

One would hope that the availability of *Journal Citation Reports* will have a salutary effect on editorial complacency. A change in a journal's citation rate or impact rate is proper reason for editorial concern, admitting that factors beyond editorial control may be responsible. Thus, a drop in the impact of the leading Soviet journal of physics, *Zhurnal Eksperimentalnoi i Teoreticheskoi Fiziki*, or a rise in the impact of *Teploenergetika* (translated as *Thermal Engineering*) may reflect a shift in interest or emphasis of research worldwide. But a change in citation rate or impact rate may just as likely reflect a change in quality of output.

Journal citation analysis can be quite complex in some cases. The problem of Soviet publications is one such case. Apart from the usual bibliographic problems encountered, one must deal with the fact that most leading Soviet journals appear in two versions, Russian and English. *Fizika i Tekhnika Poluprovodnikov* appears in English as *Soviet Physics Semiconductors*. Clearly that is not a close translation of the title, much less a transliteration. Such bibliographic casualness about titles is bad enough, but there is worse. Most of the retitled translations appear about a year after the originals. This means, if one assumes that the translation is the major stimulant of subsequent citation in Western journals, that the citable life of the Soviet literature is unfairly shortened at the outset by an overlong gestation period. And the outset is important, for if an article is going to be cited, it is most likely to be cited during the first or second year after publication. In the case of Russian journals, citations contributed by translated versions are usually out of phase with those of the rest of the literature. To assure confusion worse confounded, some of the translated versions have volume and page numbers different from the Russian originals. In our tabulations for the *JCR*, we have as far as possible compensated for these annoying vagaries.

As the data show, new journals can achieve high impact quickly. Good examples are *Cellular Immunology* (first published 1970) and *Prostaglandins* (1972). Their total 1974 citation counts were 2,809 and 1,470 respectively; their impacts, 4.848 and 5.247. Among the newer journals the 'European' journals are especially notable in this respect. *FEBS Letters* (began 1968, impact 3.049); *European Journal of Biochemistry* (began 1967, impact 3.874); *European Journal of Immunology* (began 1971, impact 4.852). We must hope that internationalisation of journals will continue. I believe that Latin-American, Asian, and African

journals would do well to consolidate in like manner to produce fewer but larger journals. It is clear that a large journal, even if less than first class, is more difficult to ignore than a smaller journal with equal and perhaps greater impact.

In some cases, however, consolidation is inappropriate and may be detrimental. Take, for example, *Journal of the American Chemical Society (JACS)* and *Journal of the Chemical Society*. The *Journal of the Chemical Society* encompasses nine different subtitled journals. If one were to consolidate comparable journals of the American Chemical Society, their total citation count would be about 183,000, almost double the 98,995 of the *JACS*. The impact of this conglomerate would, however, be only 3.381 (respectable enough) rather than 4.383. Insistence by the Chemical Society upon corporate identity for its journals by means of an identical "main title" with repeatedly retitled sections is the source of bibliographic confusion, as well as of much tedious work in sorting out citation data. It seems to me that most commercial publishers would have refused to scrap a title as well-known as *Transactions of the Faraday Society*. In my opinion, the umbrella of a corporate main title for all a society's journals does little for their individual identities.

I have avoided commentary on the performance of specific

journals, preferring to use the space granted me here for data rather than comment and speculation. And I have published many such analyses, usually on a categorical basis in *Current Contents*. All of them have had the same purpose, and lead to the same general conclusion. Science needs objective criteria for measuring the performance of journals. Citation analysis seems to offer a sound beginning. Considering the paucity of management tools available to the average science librarian—general or specialist—and considering as well the often prejudicial role of individual scientists in journal selection (we all have our favourite journals), I feel that the *JCR* data can provide a more reliable basis for journal selection than any we have had until now.

A model for ocean-floor metamorphism, seismic layering and magnetism

Maarten J. de Wit & Charles R. Stern

Lamont-Doherty Geological Observatory of Columbia University, Palisades, New York, 10964

Ocean-floor metamorphism, which overprints the pseudo-stratigraphy of ophiolite complexes in southern Chile, is best explained by a combination of hydrothermal and contact metamorphism associated with igneous activity at a spreading centre. Such metamorphism may be more important than igneous processes in producing the observed seismic layering and magnetic properties of the ocean floor.

MODELS of accretionary processes of the oceanic lithosphere integrate marine geophysical data, results of oceanic dredging, and studies of the pseudo-stratigraphy and petrology of ophiolites, recognised as sections of oceanic crust^{1–3}. An important element in these models is the relative extent to which primary igneous processes or secondary metamorphism best explain the geophysical properties of the ocean crust. In this paper we describe the overprint of ocean-floor metamorphism on the pseudo-stratigraphy of ophiolite complexes in southern Chile. The metamorphism in these and other ophiolites, as well as in the ocean floor, is better explained by hydrothermal and contact metamorphism associated with igneous processes at a spreading centre than by burial metamorphism⁴. The effects of this special type of metamorphism, as discussed below, may be more important in producing the geophysical properties of the ocean crust than the igneous processes with which they are associated.

Ocean-floor metamorphism

The ophiolite complexes in southern Chile represent the floor of a Mesozoic marginal basin⁵. Their igneous pseudo-

stratigraphy, like that of many ophiolites elsewhere, consists of pillow lavas underlain by a sheeted dyke complex in turn intruded by chemically layered gabbroic plutons (Fig. 1). The complex sequence of continued intrusion and extrusion which leads to the formation of this pseudo-stratigraphy is described elsewhere^{6,7}.

The ophiolite stratigraphy is overprinted by at least two metamorphic episodes, the second of which is a regional event associated with regional deformation, which only affects the rocks surrounding the ophiolites⁸. The associated low-grade regional metamorphism has not significantly altered the ophiolites and its effects can be easily distinguished.

The earlier phase of metamorphism is not related to regional deformation and its effects are restricted to the ophiolites. From the top of the ophiolites, the intensity of metamorphism increases downwards from zeolite facies through greenschist to amphibolite facies within a short vertical sequence of 2–3 km (Fig. 1). Completely fresh pillow lavas at the top of the sequence have not been encountered. The maximum metamorphic grade is attained within the gabbro unit where the metagabbroic rocks can be classified as amphibolites. Below this zone the metamorphic effect dies off rapidly, leaving fresh gabbros. This boundary between fresh gabbro and amphibolite is extremely irregular, deeper penetration of the metamorphic effect being concentrated along fractures, veins, shear zones and dykes. Similar effects have been observed associated with zones of deformation in some of the Italian Apennine ophiolites⁹.

Fig. 1 A schematic column for Chilean ophiolites and a model of oceanic crust. The figure was constructed with preliminary oxygen isotope data for the Chilean ophiolites provided by J. Lawrence, and published seismic¹⁹, magnetic²¹, and oxygen isotope²⁰ data which have been correlated with metamorphic zones in the model of oceanic crust.

In detail, our petrographic data indicate that at the onset of the lower boundary of the amphibolite-facies metamorphism, olivine in olivine-pyroxene gabbros breaks down to skeletal magnetite and minor serpentine. Pyroxene develops thin rims of hornblende and plagioclase remains essentially unaltered. Higher in the section, pyroxene becomes uranitized and forms iron-rich hornblende. Skeletal networks of secondary magnetite form along fractures and cleavage planes of pyroxenes and amphiboles. Successively upwards, calcic plagioclase is replaced by clino-zoisite, epidote, chlorite, and reacts with silica to form myrmekites. Throughout these states of alteration, the metagabbros retain their original coarse ophitic igneous textures. The overprinted fine-grained metamorphic textures include dendrites and symplectites of epidote, chlorite, and, amphibole; myrmekites and granophyres of low Ca-plagioclase and quartz, and widmanstätten-like textures displayed by amphiboles and opaques. Grain boundaries are often ragged

and feathery. Such textures do not conform with normal textures associated with regional (dynamothermal) amphibolite-facies metamorphism.

Above this zone, metamorphic grade decreases to the greenschist facies. Textures conform with those observed in rocks from other ophiolite terrains and from oceanic dredge hauls. Original igneous textures are not always preserved, and mineralogically the metabasalts and metadolerites can be termed spilites¹².

We interpret the observed textures to be the result of metamorphism-metasomatism during which hot aqueous solutions incongruently dissolve and reprecipitate various elements. The breakdown of olivine and the high solubility of silica relative to iron at high temperatures results in the differential removal of Si with respect to Fe. Fe remains partially *in situ* in the form of magnetite, indicating an oxidising environment. The migration of fluids containing both dissolved Si and Fe, upwards along the decreasing

Fig. 2 Model of hydrothermal-contact metamorphism at a spreading centre, as outlined in the text. The figure shows the deep penetration of hydrothermal cells close to the ridge axis and their diminution away from the main zone of igneous activity and tectonism. The deepest level of penetration of the hydrothermal cells defines the depth to the bottom of layer 3A.

thermal gradient, results in the local precipitation of secondary magnetite as well as the formation of iron-rich hornblende from pyroxene. At successively higher levels, lower temperature decreases the solubility of Si, which instigates the reaction between silica and plagioclase to form myrmekites-dendrites and quartz. At still higher levels (dykes and pillow lavas) under lower prevailing temperatures, local metasomatism causes chemical and mineralogical changes termed spilitisation, which have been described previously⁹⁻¹². At this level sulphide mineralisation is common in ophiolites¹¹ and the environment seems to be reducing (Fig. 2).

A deuteric rather than hydrothermal process has been suggested as a possible cause for such a sequence of alterations^{11,14}. Conate fluids would be expected to be enriched at the top of magma chambers; however, the estimated weight percent of juvenile waters in oceanic tholeiites is low¹⁵. Hydrothermal circulation of seawater is a more likely explanation for the large scale (volume) alteration⁸. Preliminary data from the Chilean ophiolites (J. Lawrence, unpublished data) show a decrease in $\delta^{18}\text{O}$ from 9‰ in pillow lavas and pillow breccias, to 3.5‰ in the lowest metagabbros. Less altered underlying gabbros have values of 6.5‰, more representative of fresh oceanic gabbros and basalts (Fig. 1). Such a sequence from ^{18}O -enriched to ^{18}O -depleted rocks of basaltic compositions can be explained by re-equilibration, at successively higher temperatures, with a large reservoir of non-magmatic water.

Simple burial metamorphism is unlikely to be the process responsible for these features. Oceanic heat flow data indicate that the geothermal gradient needed to produce the observed metamorphic gradient would be encountered only in a narrow zone restricted to oceanic ridges¹⁶. Bonatti *et al.*⁴ drew identical conclusions from their study of metagabbros (amphibolites) dredged from the axial valley of part of the mid-Atlantic ridge, which their calculations showed had never been buried more than 1.5 km. They concluded that such a steep metamorphic gradient could be better explained by hydrothermal and contact metamorphism at the oceanic ridges, a process ultimately related to igneous intrusion beneath and volcanism within the median valley of such ridges. We agree with their conclusions and believe that such a model explains the steep metamorphic gradient in the upper section of our and other ophiolites (that is, the Troodos, Apennine, and Bay of Islands Complexes^{4,17}) as well as sections of the oceanic crust⁸. More significantly it can also explain the rapid termination of the metamorphic effects we observe within the gabbroic layer of the Chilean ophiolite complexes.

In simple terms, the model of Bonatti *et al.*⁴ involves a hydrothermal convective cell driven by the heat from igneous intrusions (Fig. 2). Seawater penetrates the oceanic layer along zones of high porosity and structural weakness, to a depth where it is driven back by heat from the intrusion of gabbro and dykes. Extensive hydrothermal systems within active spreading axes are supported by several lines of evidence. First, heat flow observed at spreading centres is lower than theoretical predictions and is best explained by a major component of convective in addition to conductive heat transfer¹⁸. Second, it has been demonstrated that such hydrothermal convective processes are the fundamental cause of metallogenic deposits forming at ridge crests¹⁹. $^{18}\text{O}/^{16}\text{O}$ studies indicate extensive interaction of dredged metabasalt and metagabbro with ocean water²⁰. Such hydrothermal systems have been confirmed by direct observation in Iceland where the spreading centre emerges²¹.

A number of factors indicate that the residence time of the metamorphosed gabbroic rocks within the zone of hydrothermal circulation is short, implying that deeper parts of this zone are narrowly restricted to the spreading

axis. The large surface areas of the myrmekite-dendrite textures indicate rapid growth under supersaturated conditions^{22,23}. Lack of recrystallisation and annealing textures indicates a rapid decrease in local temperature or fluid phase, or both and the absence of retrograde features substantiates this. In metagabbros dredged from the ocean floor, Muehlenbachs and Clayton²⁰ reported disequilibrium between $^{18}\text{O}/^{16}\text{O}$ ratios of coexisting plagioclase and pyroxene which they attributed to a kinetic effect whereby the pyroxene does not react as rapidly as the plagioclase. Such chemical disequilibrium, like textural disequilibrium, implies that the metagabbro had been removed rapidly from the zone of effective metamorphism. Two effects which may combine to restrict the width of the deep zone of hydrothermal alteration are (1) its dependence on intrusive and tectonic activity, which are restricted to near the ridge axis, and (2) the silicification effected by the hydrothermal circulation which acts to reduce the permeability of the rocks. Hydrothermal circulation may exist within a wide area around a spreading ridge, but it is probably confined to the higher level of the oceanic crust, where it causes continued greenschist facies metamorphism and metasomatism (Fig. 2).

Our preferred model for ocean-floor metamorphism near a spreading ridge based on the above evidence is shown in Fig. 2. Deep penetration of hydrothermal fluids is restricted to a narrow zone near the oceanic ridge, with smaller convection cells concentrated at successive higher levels away from the ridge. The greatest depth of penetration of hydrothermal circulation may depend on tectonic activity or spreading rate. Deeper penetration may occur in slow spreading ridges with well developed median valleys than in fast spreading ridges without median valleys. In Chile, metamorphic effects penetrate more deeply in ophiolites in the narrower part of the original basin which may have spread more slowly²⁴. A more complete picture of regional ocean-floor metamorphism is outlined schematically in Fig. 3. This scheme includes dynamothermal metamorphism along fracture zones which is locally complex and polyphasal, as theoretically predicted by Dewey²⁵ and later demonstrated from dredge hauls by Honnorez and Bonatti²⁶. Fracture zones also contain hydrothermal circulation systems hence hydrothermal metamorphic regimes as indicated by the presence of fresh hydrothermal metallogenic deposits²⁷. Also, burial metamorphism *sensu stricto* may play an important part in those areas where sedimentation rate and sediment thickness are high, such as along Atlantic-type continental margins²⁸ and within some marginal basins along Pacific-type continental margins.

Seismic layering and remanent magnetism

Hydrothermal metamorphism may also affect geophysical properties such as the gross seismic velocities and the magnetic properties of the oceanic crust. Models of the velocity structure and lithological character of oceanic crust have been formulated by correlating velocities measured by seismic refraction methods with compressional wave velocity measurements of rocks from the sea floor and ophiolites^{17,29}. Recent seismic work has refined the oceanic layer (layer 3) into an upper layer (3A, 6.0–6.8 km s⁻¹) and a lower layer (3B, 7.0–7.5 km s⁻¹). We suggest that the transition from metagabbros into fresh gabbros marks the transition from seismic layer 3A to layer 3B (Fig. 1). This is consistent with the compressional velocity data and conforms closely with the models of Christensen and Salisbury¹⁷ and a slightly altered model of Peterson *et al.*²⁹.

In our model, this transition marks the depth to which the hydrothermal cells along the spreading ridge have penetrated. Christensen and Salisbury¹⁷ propose that an unaltered gabbro layer is added to an original metagabbro layer by intermittent off-ridge intrusion. Another model is that layer

Fig. 3 Schematic illustration of the different elements of ocean-floor metamorphism, each characteristic of a distinct tectonic environment. As new ocean crust is created it undergoes hydrothermal-contact metamorphism at the ridge axis which may be overprinted at later stages by dynamothermal-hydrothermal metamorphism along fracture zones and by burial metamorphism in areas of high sedimentation

3 is initially entirely amphibolite which becomes progressively dehydrated during further spreading⁴. Our field and textural data on the ophiolite gabbros demonstrate that the opposite sequence occurs. Fresh gabbros are intruded along a central zone and their upper sections are subsequently transformed to metagabbros. This is also supported by studies on other ophiolites such as in Newfoundland (ref. 30 and J. F. Dewey and D. S. Strong, personal communication) and Troodos⁷. Off axis welding of new gabbro and cumulate ultramafic rocks probably does occur and can account for a progressive thickening of layer 3B until a steady-state thickness is reached after about 40 Myr (ref 17).

From our data in southern Chile, it is clear that both the interface between the gabbro units and the sheeted dykes, and between the sheeted dykes and the pillow lavas is complex and gradational²⁴. The original mineralogy of these overlapping zones tends however, to be homogenised as a result of the metamorphism. Therefore, we also suggest that the boundary between layers 2 and 3 (2B to 3A) marks the transition from amphibolite facies to greenschist facies rocks. Layer 2B includes the part of the sheeted dyke complex (metadolerites) and pillow lavas (metabasalts) which are in the greenschist to prehnite-pumpellyite facies of metamorphism and layer 2A is represented by the fresh to only slightly metamorphosed (zeolite facies) pillow lavas (Fig. 1). Since the metamorphic overprint on the original complex pseudo-stratigraphy of oceanic crust may be dependent on spreading rate, seismic layering may vary from ocean basin to ocean basin.

Models for the preservation of magnetic anomalies are based on measurements of the magnetic susceptibility, the intensity of natural remanent magnetisation (NRM), and the Königsberger ratio (Qn) in rocks drilled and dredged from the ocean floor and sampled from ophiolites²¹⁻²³. These measurements suggest that fresh quenched pillow basalts with high NRM and Qn are the most likely source of the magnetic anomalies (Fig. 1)²⁴. Nevertheless, even 500 m of fresh pillow lavas are not considered sufficient to produce the measured magnetic anomalies and some contribution must be made by the underlying rocks²⁵.

Our petrographic examination of ocean-floor rocks, for which Fox and Opdyke²¹ have measured the magnetic properties, shows that amphibolitised metagabbros have a higher NRM (18.3×10^{-4} e.m.u. cm^{-3} for partially amphibolitised gabbros V25-D6-39 and 69; 29.4×10^{-4} e.m.u. cm^{-3}

from strongly amphibolitised metagabbros V25-D6-17 and 56) and Qn than either greenschist facies metabasalts (0.12×10^{-4} e.m.u. cm^{-3} for all metabasalts except V25-D5-5 which is only slightly altered to a zeolite facies) and metagabbros (5.7×10^{-4} e.m.u. cm^{-3} for all metagabbros except VD-25-17 and 56 which are amphibolites) or fresh gabbros (2.1×10^{-4} e.m.u. cm^{-3} for V25-D6-6 and 27) (Fig. 1). Amphibolitised metagabbros could contribute significantly to magnetic anomalies. They contain a high concentration for skeletal growths of secondary magnetite produced by the oxidation and breakdown of olivine and pyroxene and metasomatic redistribution of Fe. Neither completely fresh gabbros nor greenschist facies rocks contain these skeletal networks of secondary opaques.

In our model of the generation and preservation of magnetic anomalies, fresh quenched pillow lavas, basalts, and gabbros all take on the magnetic polarity prevalent during their formation at the ridge axis. Hydrothermal metamorphism alters the igneous rocks, developing amphibolites with abundant secondary opaques in seismic layer 3A, and greenschist to zeolite facies assemblages in the overlying rocks. This occurs in a narrow region restricted to the spreading centre so that the polarity of the entire rock column including fresh pillows is the same. The amphibolites move rapidly out of the deeper hydrothermal metamorphic zone which is narrowly restricted to the spreading axis, effectively quenching their metamorphic textures and NRM polarity. Continued hydrothermal activity and metasomatism is confined to progressively shallower depths away from the ridge and produces greenschists with lowered NRM (Fig. 1) in the overlying rocks. This process does not affect the deeper levels within seismic layer 3A.

With time, the rock column (Fig. 1) moves away from the ridge axis. Ocean-floor weathering and shallow hydrothermal circulation continue to reduce the NRM of the pillow lavas; however, the NRM of the lower metagabbros remains constant. This effect could possibly account for the observed decrease in the amplitude of the linear magnetic anomalies away from the ridge axis for at least 10 Myr followed by a steady amplitude in the anomalies further away from the ridge (ref. 36 and W. C. Pitman III, personal communication).

Hydrothermal circulation within fracture zones could be expected to function in a fashion similar to that at a spreading ridge, although the affected rock assemblages may not be removed as quickly from the higher metamorphic zone,

except by uplift (Fig. 3). Development of secondary opaque minerals, particularly within uplifted serpentinised bodies, would cause these rocks to acquire an overprint of the prevailing magnetic polarity. Cochran²⁷ suggested that the Romanche fracture zone trough is either a zone of reduced magnetisation, or the basement is normally magnetised along the fracture zone for a distance of 500 km. We believe that magnetic overprinting could have caused the latter alternative. Young extension fracture zones, or "leaky" transforms may be expected to give high amplitude anomalies, while prolonged hydrothermal alteration during reversals will alter such anomalies significantly.

High sedimentation rates producing thick sediment blankets will induce a regime of burial metamorphism. Such thick sediment blankets are only associated with particular tectonic environments such as some types of marginal basins, as along the Western Pacific margin, and Atlantic-type continental margins (Fig. 3). The secondary metamorphism that they produce may act to retrograde any magnetic layer in the ocean crust and decrease its NRM. This effect may be one of the reasons responsible for some quiet magnetic zones along continental margins and the absence of well defined linear magnetic anomalies in some marginal basins. Larson *et al.*²⁸ presented similar arguments to account for the absence of magnetic patterns in the northern part of the Gulf of California.

A critical factor in the production of linear magnetic anomalies according to this hypothesis is the regularity of the hydrothermal metamorphism. In a marginal basin, such as the Sea of Japan, extension may not take place along a well defined linear spreading axis, but may proceed within a more diffuse zone with active regions separated by continental blocks. We expect the hydrothermal activity will be as diffuse as the igneous activity with which it is associated. We suggest that this is an additional factor that can account for the irregularity of magnetic anomalies reported within many marginal basins.

Model of metamorphic overprint

The metamorphic overprint on ophiolite complexes in southern Chile, in which metamorphic effects grade rapidly downward from zeolite to amphibolite facies and then disappear abruptly, is better explained by a model of hydrothermal metamorphism closely associated with the zone of igneous intrusion than by the classical concept of regional burial metamorphism. The metamorphic conditions that are reached during this metamorphism are principally a function of temperature and fluid phases. Hence, if the present metamorphic facies concept is to be continued and extended to include ocean floor metamorphism, metamorphic facies must be plotted on three-dimensional diagrams in order to include fluid phase variables, principally H₂O.

The metamorphic overprint may have a more significant influence than the igneous pseudo-stratigraphy in determining some marine geophysical properties. Irregularities in the juxtaposition of the overprint on the pseudo-stratigraphy caused by various rates of spreading, sedimentation affecting hydrothermal circulation, and the linearity or irregularity of spreading activity determined by tectonic environment, all influence the variability of the geophysical properties of the rocks.

The overprint of the metamorphism determines the seismic layering of the ocean floor, seismic layer 2A consists of fresh, weathered, and zeolite facies pillow lavas, basalt and dolerite dykes; seismic layer 3A consists of amphibolite facies dolerite dykes and metagabbros, seismic layer 3B consists of fresh gabbros intruded at the ridge axis but below the greatest depth of penetration of the hydrothermal metamorphism.

The deepest levels of the metamorphism produce an oxidation zone with extensive development of secondary

fine grained opaque minerals which may enable rocks in this zone to preserve a stronger NRM than both underlying fresh gabbros and overlying greenschist, zeolite, and weathered basalts. Marine magnetic anomalies are likely to be produced by an integrated effect of layer 2A and 3A. Layer 3A is not affected by off-axis shallow-level hydrothermal circulation which weathers and spilitises the overlying basalts reducing their NRM. Thus with time this layer may become a more significant contributor to magnetic anomalies.
